

2022 KAKSHE AND BASS LAKE STEWARDSHIP REPORT

Ron Pearson, M.Sc. - Kakshe and Bass Lake Steward

ABSTRACT

The findings of all environmental water quality and biological monitoring for both Kakshe and Bass Lakes in 2022 have been summarized and compared to acceptable water quality and aquatic health benchmarks for algal friendly nutrients phosphorus and nitrogen as well as over 30 different chemical parameters. Historical trends in water quality over four decades have, with one minor exception, identified no major contamination issues that would explain why Kakshe Lake was impacted by harmful algal blooms (HABs) in both 2020 and 2021. The exception was for phosphorus at one location in Kakshe Lake, where levels have gradually started to rise and are now well above a 'Background' level. This report discusses why this happening and identifies four key actions waterfront property owners can take to reduce the likelihood of future HABs as our climate changes. Based on a KLRA-funded near-shore sampling program in 2021, we need look no farther than our own shorelines to understand why the historical monitoring at mid-lake, deep water sampling locations is not generating a true picture of water quality close to the shore. This report also identifies some insights and linkages between our changing climate and its role in the development of late season HABs in Kakshe Lake.

Executive Summary

2022 Kahshe and Bass Lake Steward Report

A comprehensive review and analysis of all historical environmental monitoring on Kahshe and Bass Lakes has now been completed and presented within annual Lake Steward Reports from 2012 through 2022. These documents as well as Executive Summaries each year have been posted on the KLRA website: <https://kahshelake.ca/Water-Quality>.

This report captures the findings from sampling and analysis of both Kahshe and Bass Lakes in 2022.

In an effort to simplify the reporting of a large amount of measurement and analysis data, the report has been structured to address the following issues/areas of potential concern for both Kahshe and Bass Lakes:

- Nutrients, Water Clarity, Temperature and Algal Growth
- Calcium Depletion
- Lake Acidification
- Metals and Other Chemical Contamination
- Dissolved Oxygen Depletion
- Benthic Health

To better understand the chemical and physical data that have been collected, the 2022 report includes an overview of the climatological factors that have the potential to influence lake conditions.

This comparison demonstrated that air temperatures in 2022 were generally similar to the three previous years and to the 30 year normal for most months, with the exception of much warmer conditions in May and to a lesser extent, August and September. In the case of precipitation, total monthly amounts were noticeably lower in May through July and above normal in August. The lower levels of precipitation in late summer in 2022 may have played a role in the absence of a blue-green algal bloom in 2022 as major late-season precipitation events in 2020 and 2021 appeared to have accelerated the leaching and run-off of algal-friendly nutrients into near-shore waters and the development of harmful algal blooms.

In 2022, the ice-out date was April 16 and the data for Kahshe Lake appear to generally follow the ice-out dates for the larger Muskoka Lakes, with no evidence of a trend towards earlier or later ice-out times on Kahshe Lake over this 135 years period.

A full discussion of the findings of DMM and MECP water quality and biological monitoring programs can be found in Section 4 of this report, and these findings are summarized in Section 5. Based on these investigations, the following conclusions have been reached regarding the six water quality indicators identified above.

Lake Health Parameter	Summary of 2022 Findings
Nutrients, Water Clarity, Temperature and Algal Growth	<p>With one exception, the 2022 water quality monitoring of Kahshe and Bass Lakes by the DMM and the MECP has not identified any major water chemistry issues or trends in terms of algal friendly nutrients – nitrogen and phosphorus. The only exception was an increase in mid-lake total phosphorus levels at one location in Kahshe Lake and this has resulted in the 2022 levels at the DMM’s Main site near Hens and Chickens now reaching the DMM’s Threshold level for Kahshe Lake. This likely due to mixing of higher phosphorus-laden waters via current flow from Bass Lake, as it is now known that the east end of Kahshe Lake has higher levels of total phosphorus due to its proximity to Bass Lake which typically has about twice the levels of total phosphorus.</p> <p>Trends in water temperature and clarity which can be indicators of favourable algal growth conditions also were examined and there was no evidence of a warming trend based on water temperature measurements dating back to the early 1980s. Water clarity also has remained fairly steady over this four decade period.</p> <p>And finally, the good news is that although the Simcoe-Muskoka area experienced HABs in 10 lakes/water bodies in 2022, there were no confirmed HABs on Kahshe or Bass Lakes in 2022.</p>
Calcium Depletion	<p>Decreasing lake water calcium concentration is an emerging concern for lakes on the Precambrian Shield in Ontario due to its impact on the reproduction and survival of zooplankton and other aquatic species that are important components of the aquatic food chain.</p> <p>The 2022 data confirm that there is no detectable trend towards decreasing levels of calcium in either Kahshe or Bass Lakes. However, as levels of calcium are fairly close to the aquatic growth limiting threshold of 1.5 mg/L and as this threshold value would not be protective of all aquatic organisms, continued vigilance is necessary.</p> <p>This is underscored by late season population explosions of <i>Holopedium</i> in Kahshe Lake in both 2021 and 2022. These pea sized, jelly-like orbs are not known to be toxic, but are an uncomfortable nuisance as they can be felt against your skin while swimming.</p>
Lake Acidification	<p>The waters of Kahshe and Bass Lake have acidity (pH) levels that are within a normal range and there is no evidence of an increasing or decreasing trend in acidity over the two decade monitoring period.</p> <p>While the pH findings represent good news, it should also be recognized that the waters of Kahshe and Bass Lakes have low levels of alkalinity, and as such, are more susceptible to acidification, as the ability of the water to buffer the acid input is low.</p>
Metals and Other	<p>The analysis of over 30 additional anions, cations and other chemicals by the DMM in 2022 has identified no aquatic toxicity/health issues. While there were some minor exceedances of chronic (long term) health protection benchmarks established by the</p>

Lake Health Parameter	Summary of 2022 Findings
Chemical Contamination	<p>MECP and other agencies in the early years, most of these exceedances were likely due to sampling or laboratory artifacts, as more recent sampling has shown concentrations that are in the expected range for non-impacted surface water bodies in Ontario.</p> <p>However, it should be noted that in several cases the laboratory detection limits are at or close to aquatic protection values, and as a result, firm conclusions regarding these substances cannot be drawn. This situation was exacerbated by the increase in some Detection Levels in 2021 and 2022</p> <p>In the case of aluminum, the aquatic benchmark has been exceeded in Bass Lake in several years; however, the benchmark consists of a range in values and must be evaluated based on the pH and DOC concentrations in lake water. Based on these findings, the levels of aluminum need to be followed carefully in future monitoring to ensure that the waters of Kabshe and Bass Lakes are safe from an aquatic perspective.</p>
Dissolved Oxygen Depletion	<p>Dissolved oxygen (DO) in lake water is important, as it is essential for the survival of all aquatic organisms. A lack of oxygen in the lower layers of the lake (referred to as being anoxic) also can cause mobilization (release) of phosphorus from sediments.</p> <p>Dissolved oxygen is influenced by seasonal temperature changes that factor into lake stratification, the process whereby lake water is turned over (mixed) in the late fall and again following the winter ice melt and then begins to stratify through the spring, summer and fall as water temperature increases at the surface and DO levels decrease with increasing depth.</p> <p>The DO at increasing water depths in both Kabshe and Bass Lakes for 2022 revealed that:</p> <ul style="list-style-type: none"> ▪ In Kabshe, the DO levels follow the historical trend of falling below the PWQO at a depth of around 5m below the surface. However, unlike the earliest data from the 1980s and 1990s, they begin gradually recovering (increasing) in 2022, following the trend that was observed in the 2000-2009 and 2010-2019 decades. This is good news in terms of aquatic life at lower depths of the lake. ▪ In Bass Lake, by early August, the 2022 DO levels are essentially similar to the historical records of DO levels down to about 2m depth and then decrease gradually through the 3m depth, falling below the PWQO just below the 2m depth. This is a concern from both an aquatic health and phosphorus mobilization from sediment perspective.
Benthic Health	<p>Benthic health assessment is now undertaken annually, as Kabshe Lake is now considered a 'Vulnerable' lake due to the appearance of HABs in 2020 and 2021. The types of benthos indicate the health of both the riparian and littoral zones as these</p>

Lake Health Parameter	Summary of 2022 Findings
	<p>areas can be impacted by snowmelt, runoff, sedimentation and other development activities.</p> <p>Collected benthos are grouped into seven different categories based on their typical response to environmental contamination and are then compared to the Muskoka average. The 2022 findings confirmed that species richness (biodiversity) was good and that species that thrive in good water quality were above the Muskoka average while species that thrive under pollution stress were below the Muskoka average, both of which are favourable findings.</p>

Based on the 2022 water quality and benthic monitoring of Kahshe and Bass Lakes by the DMM and the MECP, with a few exceptions, no major water quality issues or trends were identified. However, given the documented occurrence of HABs in Kahshe Lake in both 2020 and 2021 as well as the late season population explosion of a zooplankton organism (*Holopedium*) known to be associated with decreasing levels of available calcium in Muskoka region lakes, it is clear that the tracking of water quality via the mid-lake, deep water sites of the DMM and MECP is not providing a fully representative assessment of water quality in the near-shore environment where algal blooms have been documented..

In the case of Bass Lake, the DMM has identified it as a ‘Vulnerable’ lake and has undertaken a more comprehensive Causation Study in 2021. Hopefully, the findings from those investigations will shed light on the cause of the elevated total phosphorus which has been recorded in Bass Lake since monitoring by the DMM began back in the early 1980s. A draft of the DMM’s investigation was released in late 2022 and comments were provided by the KLRA. The final report has not yet been released.

So, for Kahshe Lake, where do we go from here?

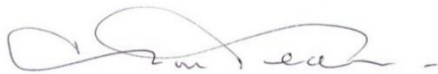

Kahshe Lake also has been identified by the DMM as a ‘Vulnerable’ lake and a DMM-funded Causation Study will be undertaken when funds and staffing are available following the completion of Causation Studies on the first group of vulnerable lakes (including Bass L). Given the uncertainty regarding the implementation of a DMM-funded Causation Study and the concern of property owners regarding the late season HABs in 2020 and 2021, the KLRA funded a Conservation Committee project in 2021. The purpose of this study was to explore the chemistry of near-shore waters over the spring and summer season in an effort to better understand why Kahshe Lake has been impacted by HABs in spite of reasonably low and unchanged phosphorous levels reported by the DMM and MECP over the past 40 years.

The findings from this Near-Shore Water Sampling Project (NSWSP) have been published in a final report available on the KLRA Water Quality web portal. The NSWSP identified some very useful insights and linkages between our changing climate, its impact on water quality and the development of late season HABs in Kahshe Lake. Briefly, the NSWSP demonstrated that:

- Mid-lake, deep water sampling in the spring of the year is a reasonable way to track long-term, historical changes in water quality but is not providing a very accurate assessment of water quality in the near-shore environment where HABs have been documented.
- The mid-lake, deep water sampling also has failed to capture much higher total phosphorus levels in the east end of the lake, as there are no DMM sampling sites in that area.
- Levels of algal-friendly nutrients (phosphorus and nitrogen) tend to increase and fluctuate as the season progresses, further limiting the relevance of the spring sampling of mid-lake sites in terms of assessing the potential for HAB development.
- The near-shore water chemistry findings for some algal-friendly nutrients appear to be associated with effluents from human & animal waste sources and are known to be linked with HABs.
- Although more study is warranted, the near-shore findings point to accelerated leaching and/or runoff of soil-borne nutrients due to a changing climate which is resulting in more intense late season rainfall events.

Although we have virtually no control over the change that is affecting our climate, there are actions we can and must take to minimize the accelerated leaching of algal friendly nutrients to our shoreline water and thereby reduce the potential for future algal blooms. These actions have been thoroughly explored by the Conservation Committee and are summarized below:

- 1. Divert roof drainage and runoff from paths and other hard surfaces away from your septic system and the shoreline. If necessary, direct rain water into rock-filled drainage pits.**
- 2. Keep most of your shoreline as natural as possible with a zone of trees, shrubs or tall grass between the shore and any lawn area to discourage grazing by Canada geese and to reduce soil & goose poop runoff into the lake.**
- 3. Have a licensed professional pump out and inspect your septic system for failures and deficiencies every 3-5 years and more often for aging systems installed pre-2000. The Town will be inspecting in 2023, but we don't need to wait until then and be subject to system shutdown until failing systems are repaired.**
- 4. Don't use phosphorus or nitrogen fertilizers or cleaning agents anywhere near the shore.**

Ron Pearson, M.Sc.

Kahshe and Bass Lake Steward - Conservation Committee

1.0 Kahshe Lake Stewardship Mandate

As a standing member of the Kahshe Lake Conservation Committee, the roles and responsibilities of the Lake Steward include:

- Educating the residents and other users of Kahshe and Bass Lakes on how to **preserve and improve** the quality of both lakes and their shorelines.
- Monitoring the water quality of both lakes and keeping the association members up to date on the results of all analytical and biological monitoring programs.

In accordance with this mandate, a comprehensive review and analysis of all historical environmental monitoring on Kahshe and Bass Lakes has now been completed and presented in annual Lake Steward Reports from 2012 through 2022. These documents as well as Executive Summaries are posted on the **Lake Health** tab of the KLRA web-site <https://kahshelake.ca/Water-Quality>. Prior to 2012, a few Lake Steward reports were located; however, this was prior to development of the KLRA web site, and as such, these reports are not currently on-line.

Before moving on to discuss the chemical and biological monitoring since 2012, it is important to discuss another water quality parameter that is **not** being routinely monitored in either lake or at the public beaches by any organization - coliform bacterial contamination. If you are drinking water from the lake – **which is strongly not recommended** - and want to ensure that your filtering system is functioning properly, you can submit a sample of water to the Simcoe Muskoka Health Unit for coliform analysis. The contact info is:

- 2-5 Pineridge Gate, Gravenhurst, ON, P1P 1Z3. PHONE: 705-684-9090, FAX: 705-684-9887.

Anyone who suspects that a neighbouring septic system is in need of pumping or improved management can also take a sample from the lake and submit it to the Simcoe Muskoka Health Unit. If this is something you would rather not do, then you should inform the Building Department at the Town of Gravenhurst of your concern and follow-up with them to determine if action is/was/will be undertaken.

Given the importance of and responsibility for maintaining fully functional septic systems and keeping septic-sourced fecal coliform levels as low as possible, the following information has been extracted from a *Good Neighbour Resource Hand book* article which was updated in 2014 by the KLRA's Conservation Committee.

Your septic system is a sewage treatment facility that requires careful attention to design, construction, operation and maintenance. **As a property owner, this is your responsibility.** In Ontario, the specifications for construction and maintenance of sewage systems with a flow of less than 10,000 litres per day are regulated under the *Ontario Building Code*, and municipalities are responsible for the inspection and approval of all septic installations. For Kahshe and Bass Lakes, the Building Department of the Town of Gravenhurst is the agency with this responsibility. In addition to permitting the installation of septic systems, the Town operates a septic re-inspection program as follows:

- the re-inspection on Kahshe Lake is carried out every 5 years;
- it consists of a trained student visiting most (but not always all) properties and carrying out a visual inspection of the tank and bed;

- if there are visual signs of failure of the leaching bed, they leave a notice and the Building Department follows up with a letter requiring a pump-out and system inspection with a receipt from a licensed pumper to confirm that it has been carried out;
- if the visual signs point to a **serious** failure, the Building Department issues a stop order until evidence is provided that the problem has been corrected.

Unfortunately, there is no systematic process for re-inspections based on when the septic system was installed or on previous re-inspection findings. As it currently stands, the last Town inspections for road access properties was conducted in 2013 and in 2009 for water access properties. The COVID-19 pandemic further delayed planned re-inspection in 2021 and the program was aborted in 2022 due to staffing issues. Given this performance history, cottage owners are encouraged to report any suspected problems to the Building Department so they can follow up with an inspection of the system.

The KLRA has been asked on a number of occasions to include coliform monitoring as part of the chemical and biological sampling programs carried out by DMM and for MECP by the Lake Steward. Although coliform analysis was included as part of the Near-Shore Water Sampling Project which was funded and undertaken by the KLRA in 2021, this was a once only sampling and will not be carried out on a routine basis for several reasons:

- as a KLRA citizen volunteer, I am not qualified as a medical or public health authority to interpret or advise on the findings from this type of sampling program.
- Coliform concentrations are highly variable, which would make any predictive type of notification regarding use of the water for consumption or swimming virtually impossible.
- Given the length of time it would take to collect, submit and receive the results from this type of monitoring program, any benefit would be limited, as detrimental health effects would already have taken place by the time the results were received.

2.0 Overview of Climatic Factors and Water/Ice Conditions

In order to better understand the chemical and physical data that have been collected and their relationship (if any) to weather conditions, this year's report again includes an overview of average monthly air temperature and monthly total precipitation that have the potential to influence the lake monitoring findings. These findings have been compared to the data from 2019 and 2020 as well as to the 30 year normal results.

Air Temperature and Precipitation

Air temperature and rainfall records from the Beatrice climate station were evaluated. The charts below show the average daily mean monthly air temperature and total monthly precipitation (rain + snow) for 2022 and for the two previous years for comparison. These results are also compared to the 30 year (1981-2010) normal monthly temperature and precipitation.

This comparison demonstrates that air temperatures in 2022 were generally similar to the three previous years and the 30 year normal for most months, with the exception of much warmer conditions in May and to a lesser extent, August and September. In the case of precipitation, total monthly amounts were noticeably lower in January, March, May through July and well above normal in August. These findings were discussed more thoroughly in terms of their role in the development of late season blue-green algal blooms in both 2020 and 2021 in the 2021 Near Shore Water Sampling Project carried out by the Conservation Committee with the financial support of the KLRA. In 2022, the lower levels of precipitation in mid to late summer may have played a role in the absence of a blue-green algal bloom as in 2020 and 2021 when late season precipitation was well above normal in 2021 and above or just below normal in 2020.

Ice-Out Times

Although there are no DMM or MECP records for ice-out times on Kahshe or Bass Lakes, a publicly available record for ice-out times of Muskoka Lakes (Rosseau and Joseph) dating back 125 years was located. These data from 1886 through 2016 have been charted below using Julian Day, which is the number of days after January 1 each year. Although a trendline based on the assumption of a linear relationship does slope toward an earlier ice out times over this 125 year period, this trend was not statistically significant, with an R-squared value of only 0.0197.

To give some perspective on how ice-out conditions on Kahshe Lake compare with corresponding dates from Muskoka Lakes, data generated by R. Cronin from the Deep Bay area of Kahshe Lake have been located for the period from 1987 through 2019. This database has been updated with ice-out dates for Kahshe Lake based on personal records (R. Pearson) from 2020 through 2022, and these dates have been plotted in the chart below (red bars). In 2022, the ice-out date was April 16. The data for Kahshe Lake appear to generally follow the ice-out dates for the larger Muskoka Lakes and as for the trend, there appears to be no evidence of a trend towards earlier or later ice-out times on Kahshe Lake over this 35 year period. Attachment 2 provides the ice-out dates for Muskoka and Kahshe Lakes which were used to generate this chart.

3.0 Overview of Environmental Monitoring

Kahshe and Bass Lakes are being monitored for water quality and biological functioning parameters under two main initiatives as outlined below:

Lake Partner Program (LPP) – MECP – Kahshe Lake Only

This program is operated by the Ontario Ministry of the Environment, Conservation and Parks (MECP) through the Dorset Environmental Science Centre. Under this program, water sampling and

measurement of water clarity on Kahshe Lake is conducted on behalf of the MECP by your Lake Steward every year. The program consists of the following activities:

- **Water clarity measurements**

Clarity of the water is measured every two weeks during the ice-free period at three locations using a Secchi disc, and these findings are forwarded to the MECP for compilation and comparison with other lakes in Ontario.

- **Water quality testing**

Water is sampled from the same three locations on Kahshe Lake in May each year and sent to the MECP where it is analyzed for total phosphorous and calcium.

Lake System Health Program (DMM) – Kahshe and Bass Lakes

This program is one of several components of a larger Muskoka Water Strategy which is operated by The District Municipality of Muskoka (DMM), with support from the Muskoka Watershed Council (MWC), the MECP and several other participating agencies.

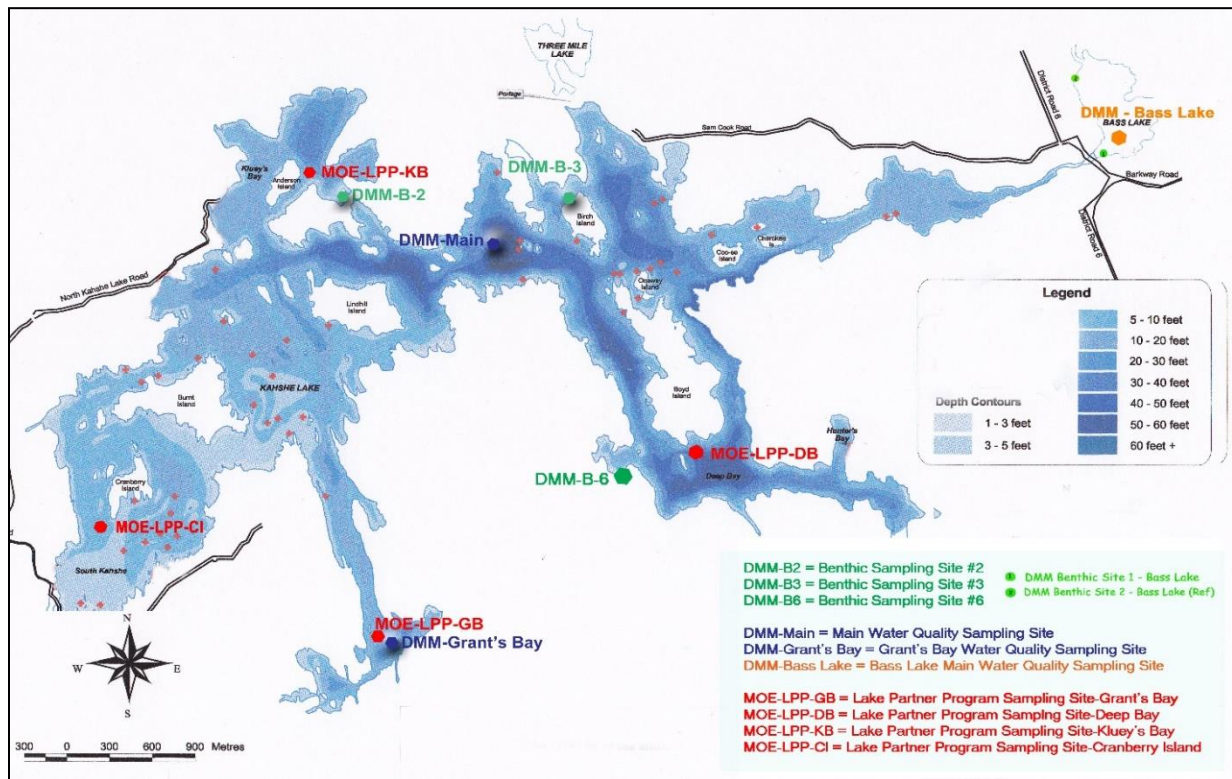

The monitoring program consists of 193 sampling sites on 164 lakes on a rotational basis. The program was designed to deliver a monitoring program which would establish a long-term record of key water quality parameters so that trends in water quality and lake system health could be identified and appropriate management decisions taken to protect lake water quality. For Kahshe and Bass Lakes, the DMM program consists of the following activities which have been conducted every second year for Kahshe Lake and every third year for Bass Lake:

- Water sample collection for total phosphorus and a suite of other physical and chemical parameters in May/June (2 sites in Kahshe Lake and 1 site in Bass Lake);
- Secchi disc depth measurements collected in May/June and August (2 sites in Kahshe Lake and one site in Bass Lake);
- Temperature and dissolved oxygen at increasing water depths taken in May/June and August (2 sites in Kahshe Lake and 1 site in Bass Lake);
- Benthic invertebrate sampling at one of three sites in Kahshe Lake in August each year from 2004 through 2007, 2011 through 2015 and 2019-2022 and in Bass Lake in 2016 through 2021.

Although water quality and benthic sampling of Kahshe and Bass Lakes in 2022 would not normally have been carried out, it was conducted to further assess water quality, as both lakes have been determined to be “Vulnerable” due to either elevated levels of total phosphorus (Bass L) or to the documented presence of a blue-green algal bloom (Kahshe) in both 2020 and 2021.

The locations of water sampling and benthic monitoring on both lakes have been shown on Figure 1 below.

Figure 1: Map Showing 2019 MECP and DMM Sampling Locations on Kahshe and Bass Lakes

4.0 Results of Monitoring on Kahshe and Bass Lakes

In this report, the results have been presented in several sections to focus on the main parameters of concern to the health of our lakes. Because both the DMM and the MECP include sampling of some of the same parameters, this report also compares the findings from each agency. The main components of this report will address the following main areas of interest/concern in terms of water quality:

- Algal Friendly Nutrients/Other Causal Factors in Algal Growth
- Calcium Depletion
- Lake Acidification
- Metals/Other Chemical Contamination
- Dissolved Oxygen Depletion
- Benthic Health

4.1 Algal Friendly Nutrients/Other Causal Factors in Algal Growth

Harmful algal blooms are a global water quality issue and are the result of ongoing nutrient (nitrogen and phosphorus) loading from watersheds (Downing et al., 2001; Elmgren, 2001; Conley et al., 2009; Smith and Schindler, 2009; Brookes and Carey, 2011; and Paerl et al., 2011). Climate change which can result in warmer temperatures, changes in the frequency and intensity of precipitation and stronger stratification (Jöhnk et al., 2008; Wagner and Adrian, 2011; Carey et al., 2012; and Posch et al., 2012) also play a causal role. Adding to the complexity of algal bloom development is the fact that algae also play a role in both nitrogen and phosphorus cycling within the water column (U.S. EPA, 2008); in the fixation of nitrogen from the atmosphere and in the release of phosphorus from sediments under low

oxygen conditions. Micronutrients such as iron, molybdenum and copper also are involved in the cycling and release of algal friendly nutrients and can affect the development of an algal bloom.

The most harmful, blue-green algae, are actually cyanobacteria. They are primitive microscopic organisms that have inhabited the earth for over 2 billion years. They are bacteria, but have features in common with algae. Although often blue-green in colour, they can range from olive-green to red. Blue-green algae occur naturally in a wide variety of environments including ponds, rivers, lakes and streams. For more information on these organisms and their impacts on lakes in Ontario and other areas, refer to fact sheets published by the Ontario Environment Ministry (2014) and Municipal Affairs and Environment, Newfoundland and Labrador (2019).

Why are we concerned about the development of blue-green algal blooms? Because blue-green algal blooms can produce toxins that pose a health risk to both humans and animals (Hudnell, 2008). The blooms also negatively affect the appearance and aesthetic qualities of the lake and this is likely to impact recreational enjoyment and reduce property values.

The severity of symptoms and the level of risk to health depend on how you are exposed to blue-green algal toxins. Human health effects from contact with these toxins may include:

- itchy, irritated eyes and skin from direct contact through activities such as swimming and water skiing; and,
- flu-like symptoms, such as headache, fever, diarrhea, abdominal pain, nausea and vomiting if large amounts of impacted water are ingested.

To give a better idea of the potential impact of a blue-green algal bloom, a copy of the Health Unit's 2020 advisory to the property owners on Kabshe Lake following a late-season bloom in the vicinity of Oak Road has been shown below:

- The health unit advises residents and businesses not to drink the water from this lake and to take the following precautions:
- do not use the lake water for drinking or for food preparation including breastmilk substitute (infant formula), even if it is treated or boiled;
- do not cook with the lake water because food may absorb toxins from the water;
- do not allow pets or livestock to drink or swim in the water where an algae bloom is visible; and,
- do not eat the liver, kidneys and other organs of fish caught in the lake and be cautious about eating fish caught in water where blue-green algae blooms occur.

Based on the foregoing discussion, the most obvious question is how can the potential for harmful algal blooms development be minimized? There are essentially two main drivers in the formation of harmful algal blooms - nutrient enrichment and warming waters. The first is within our control while the second is associated with a changing climate. In the case of nutrient enrichment, the main causal factors in algal growth are phosphorus and nitrogen. For lakes like ours, which have no immediate inputs from industrial, municipal or agricultural operations, nitrogen and phosphorus enters primarily in these ways:

- from septic system effluents
- from lawn and garden fertilization
- from land-clearing/disturbance and soil/water runoff to the lake
- from atmospheric inputs (mainly nitrogen via rainfall and dust)

- from aquatic and semi-aquatic wildlife activity, and
- from re-suspension of minerals from rock/sediments as part of phosphorus and nitrogen cycling.

Those sources that to some degree are within our control are highlighted in yellow above.

The main focus of water quality monitoring in Muskoka and Ontario by both the DMM and the MECP has been to track the quality of the water in terms of its total phosphorus levels. This in turn has served as a driver of shoreline management and property development strategies. However, emerging research shows that nitrogen is more involved in harmful algal growth than originally thought (Great Lakes Commission, 2017).

While nutrient enrichment is important, it is not the only factor involved in the promotion of harmful algal growth. Blue-green algae thrive in areas where the water is shallow, slow moving and warm, but they may also be present in deeper, cooler water. Accordingly, this section has been structured to examine the three main causal factors (excluding light which is essential for photosynthesis) in the development of harmful algal growth: **phosphorus, nitrogen and water temperature**.

The analysis in this section also includes water clarity, as although it's more a symptom of nutrient enrichment and degraded water quality than a fundamental driver of algal growth, it can provide an early warning for lake water conditions that are susceptible to algal growth.

PHOSPHORUS

In the 1960s and 70s, many North American rivers and lakes were experiencing rapid declines in water quality. Industrial and municipal effluents were stimulating the growth of algae and other aquatic plants (termed 'eutrophication') leading to unsightly mats of green sludge, oxygen depletion, massive die-offs of fish and other aquatic life, and problems with the taste and odour of municipal drinking water.

The public, industry, and all levels of government agreed that something had to be done. However, there was disagreement over the most effective course of regulatory action because at the time, scientists and policymakers were still debating which nutrients were most responsible for eutrophication.

In the late 1960s and early 70s, David Schindler, a Canadian limnologist oversaw a number of whole-lake experiments designed to determine which nutrient (out of nitrogen and phosphorus) was primarily responsible for eutrophication. His studies clearly demonstrated that phosphorus was the main contributor.

As a result of that work and other studies, the main focus of the lake monitoring programs in Ontario has been on measuring total phosphorus concentrations and linking the findings to management strategies. In Muskoka, the DMM evaluates the responsiveness of lakes in Muskoka to input and mobility of phosphorus as it enters the lake from human and natural sources. As demonstrated in previous reports, both Kahshe and Bass Lakes are considered moderate in terms of their sensitivity to phosphorus. This sensitivity rating also factors into the setting of a total phosphorus threshold for lakes in Muskoka based on limiting the increase in of total phosphorous levels above a pre-determined background value. This threshold value is set equal to the pre-determined background concentration plus an additional 50%. For example, the pre-determined background concentration of total phosphorus in Kahshe Lake is 9.5 µg/L. This results in a threshold concentration of 14.2 µg/L (i.e. [50% of 9.5] + 9.5 = 14.2). The background concentration in Bass Lake was determined to be 20.6 µg/L, resulting in a calculated threshold level of 30.9 µg/L.

If the lake’s measured and modelled phosphorus concentrations over a 10-year period are greater than its threshold value, then the lake is considered “over threshold” and actions may be initiated to reduce the amount of phosphorus entering the lake from its watershed. As noted in previous reports, neither Kahshe nor Bass Lakes have 10-year averages greater than threshold. However, the DMM has now completed their review of the water quality model that has been used to set threshold levels. They have also declared both Kahshe and Bass Lakes as ‘Vulnerable’, based on elevated total phosphorus levels (Bass L) and the documented presence of a blue-green harmful algal bloom (Kahshe in 2020 and 2021). As a result of this ‘Vulnerable’ status, the DMM now conducts water quality and benthic sampling and analysis every year in both Kahshe and Bass Lakes.

The DMM’s total spring phosphorus results for 2021 in Kahshe Lake as well as those of the past 38 years are shown in Figure 2 below:

Figure 2:

The DMM’s 2022 total spring phosphorus results for Bass Lake are shown below in Figure 3:

Figure 3:

These findings can summarized as follows:

- In both lakes, there has been no long term trend in total phosphorus concentrations over the past 40 years; however, unlike Bass Lake, commencing in 2017, there has been a very gradual increase in total phosphorus in Kabshe Lake with the 2022 levels now well above ‘Background’ and at the ‘Threshold’ level of 14.2 µg/L.
- Historically, the total phosphorus levels in Bass Lake are about twice as high as those in Kabshe Lake, with levels of total phosphorus falling marginally above or below the ‘Background’ level of 20.6 µg/L.
- While there is no clear reason for the gradual increase in total phosphorus in Kabshe Lake over the past few years, this is likely associated with increased current flow from Bass into Kabshe, as it was clearly demonstrated in the 2021 Near-Shore sampling program, that total phosphorus levels are higher in the eastern areas of Kabshe close to the inflow from Bass Lake via the Kabshe River and decline with increasing distance to the west from Bass Lake. A similar trend of increasing iron concentrations in Kabshe during this time period supports this rationale, as like phosphorus, iron levels in Bass Lake are historically higher in Bass Lake than in Kabshe Lake.
- A comparison of the total phosphorus concentrations determined via the DMM and MECP sampling programs have yielded very similar findings, with most of the differences in phosphorus likely due to different spring sampling dates which would be influenced by the degree of lake stratification (turnover).
- While the mid-lake, deep water sampling sites on Kabshe Lake generate an excellent historical record of total phosphorus concentrations for trend analysis, the findings of the 2021 KLRA-funded Near Shore Water Sampling Project demonstrated two important weaknesses in this historical record:
 - it fails to capture higher total phosphorus concentrations at the East end of the lake which has not been sampled via the DMM program; and

- the mid-lake levels are not representative of the higher and more variable near-shore total phosphorus levels where algal blooms have been identified.

As noted above, Kahshe Lake also was sampled and analyzed for total spring phosphorus under the Lake Partner Program (LPP). Figure 4 below shows the total phosphorus levels at the three LPP sampling sites in Kahshe Lake for 2022. The historical findings dating back to 1994 for the LPP program and to 1983 for the DMM results also are presented for comparison purposes.

Figure 4:

This comparison confirms that:

- From 2003 on, total phosphorus concentrations determined via the DMM and MECP sampling programs (both of which are analyzed by the MECP's Dorset laboratory) have yielded very similar findings, with most of the differences in phosphorus likely due to different spring sampling dates which would alter the degree of lake stratification (turnover) and mixing.
- Prior to 2003, the variability is likely attributed to sample collection procedures, in particular the filtering of water samples to remove zooplankton and other biological material in the water column.

NITROGEN

In a recently published document (Great Lakes Commission, 2017) on the role of nitrogen in the formation of harmful algal blooms, the current knowledge was summarized and is further discussed below. While this work was focussed on algal blooms in Lake Erie, the findings appear applicable to smaller freshwater bodies such as Kahshe and Bass Lakes.

Based on their work, nitrogen dynamics in aquatic systems was found to play a role in understanding both algal biomass trends (i.e. the size/extent of bloom development) and potential toxicity. For example, nitrogen additions can increase both biomass and toxin production in algal blooms, but at different rates depending on the form of nitrogen. (Harke et al., 2016).

In water, nitrogen occurs in several different dissolved forms. These forms influence communities of algae and cyanobacteria in different ways, based largely on their abilities to convert the different nitrogen forms into biomass and compete with other organisms. Regardless of the form, cyanobacteria must convert nitrogen to ammonium (NH_4^+) within the cell before they can use it for biomass or toxin production. Ammonium is also the easiest nitrogen form for primary producers to acquire and transport into the cell. Nitrate and nitrite ($\text{NO}_3^- / \text{NO}_2^-$) must be actively transported into the cell and then converted to ammonium, which, in turn, requires energy and micronutrients, such as iron. The differences in nitrogen bioavailability for algal growth are graphically summarized in Figure 5 below:

Figure 5:

(adapted from Harke et al. 2016 as presented in Great Lakes Commission, 2017)

As noted earlier, the primary sources of nitrogen to inland lakes like Kajshe and Bass would be from septic system discharge and soil erosion and leachate migration from fertilized lawns/gardens. Residue from bird and aquatic animal feces, plant decay (leaves, aquatic weeds) and to a lesser extent from atmospheric deposition also contribute, especially in areas where food sources like lawn grass are available.

The nitrogen monitoring results for the two forms of nitrogen that are analyzed by DMM have been charted below in **Figures 6 and 7**.

Figure 6:

Figure 7:

The results of this analysis have been summarized below.

- No evidence of a concentration trend in either of the two analyzed forms of nitrogen has been detected in Bass or Kahshe Lakes over the years dating back to 2004.
- In contrast to total phosphorus, the concentrations of nitrate + nitrite in Bass Lake are generally lower than the corresponding analysis results for Kahshe Lake; and as noted in Figure 8 below, this is not the case for total nitrogen, where levels in Bass Lake are always higher than in Kahshe Lake.
- In all cases, the reported nitrogen concentrations are well below any aquatic benchmarks that have been set to protect sensitive aquatic species.
- No algal growth benchmarks for either form of nitrogen have been located, as the linkage between phosphorus, nitrogen and water temperature is too complex to set individual nutrient benchmarks.
- While not shown above, the findings from the KLRA-funded Near-Shore Water Sampling Project conducted in 2021 demonstrate that nitrogen concentrations in the near-shore environment are often considerably higher than these spring-sampled mid-lake levels, often increase or decrease as the season progresses and have likely contributed to the harmful blue-green algal bloom that was documented in 2021. This is discussed in greater detail in the 'Algal Growth' section.

Figure 8:

WATER CLARITY

While the linkage between total phosphorus concentrations and water clarity are typically weak in tea coloured waters where clarity also is impacted by dissolved organic carbon (DOC), both sampling programs have monitored clarity via the Secchi disc method.

The DMM’s 2021 water clarity levels for both lakes have been compared with the historical results dating back to 1980s in Figure 9 below.

Figure 9:

In this comparison, Bass Lake is represented by the dark blue columns while the Secchi data from the Main Site on Kahshe Lake are shown via the light blue columns. The findings from this comparison are summarized below:

- Water clarity in Bass Lake in 2022 was slightly better than in 2021, but generally similar to historical measurements dating back to 1981.
- Water clarity in Kahshe Lake in 2022 was about the same (lower in the spring and higher in late summer) as in 2021 and generally similar to historical measurements dating back to 1983.
- Water clarity is noticeably better in Kahshe Lake than in Bass Lake, most likely due to the more tea coloured nature of Bass Lake - as confirmed by slightly higher Dissolved Organic Carbon [DOC] levels in Bass Lake.

To further explore the water clarity in Kahshe Lake as determined by the DMM, the MECP’s Lake Partner data for water clarity at the three sampling sites in Kahshe Lake also were charted for comparison. The findings are shown below in Figure 10.

Figure 10:

In contrast to the findings in previous years, water clarity in Kahshe Lake as measured by the DMM was slightly less in both 2021 and 2022 compared to the water clarity measurements from 2019. However, water clarity in both years was similar to historical clarity measurements.

In looking at the MECP’s LPP measurements, the trend of greater clarity compared to DMM clarity measurements that was recorded from 2011 through 2017 was not repeated in the years from 2019 through 2022. This may be related to the methodology for recording water clarity, as the DMM measurements are the average of two sampling events while the LPP measurements by the Lake Steward represent an average of 9-10 measurements at each site over the period from May through October. Another possible reason for the divergence is that DMM measurements are taken irrespective of weather conditions while those taken by your Lake Steward are more typically taken during sunny days when water clarity is enhanced by sunlight penetration into the lake – i.e. the Secchi disc is more visible under sunny conditions.

WATER TEMPERATURE

Another parameter that is involved in algal bloom development is water temperature, as warm water increases the rate of photosynthesis and promotes algal growth. Water temperature is important for several other reasons:

- It affects the solubility of oxygen in water.
- It affects the metabolic rates, life cycles and the sensitivity of all aquatic organisms to parasites and disease.
- It factors into the classification of a lake as a cold or warm water body (both Kahshe and Bass are considered warm water lakes – i.e. not a Lake Trout Lake).

The DMM water temperature readings at increasing depths in both Kahshe and Bass Lake data dating back to 1988 have been plotted in the four charts below (Figures 11-14). In an attempt to explore any trends in water temperature, the 2022 results have been compared with historical means grouped over three time periods:

- Pre 2000 (1980s and 1990s)
- The decade of 2000-2009
- The decade of 2010-2019

Figure 11:

Figure 12:

It is apparent from Figures 11 and 12 that:

- Water temperature in the spring of 2022 in Kahshe Lake was noticeably warmer down to a depth of 5m and slightly cooler than temperatures recorded at depths from 5 to 10m in all previous averaging periods; below 10m, the 2022 results were similar to those in the past.
- By August 2022, the temperature at all depths generally matched the historical trend of decreasing temperature with increasing depth and revealed no evidence of increasing lake water temperatures over the past four decades.

The water temperature findings for Bass Lake in both Spring and Summer are presented in Figures 13 and 14 below:

Figure 13:

Figure 14:

It is apparent from Figures 13 and 14 above for Bass Lake that:

- In the spring of 2022, Bass Lake was noticeably warmer in the top 2-3m compared to water temperatures in this surface layer in all previous years.
- However, by August 2022, the temperature in the top 2m was similar to values recorded in the 1980s and 1990s and slightly cooler than in the two decades later (2000-2009 and 2010-2019).
- Based on these records, there appears to be some evidence of an increase in water temperature down to a depth of 3m in the two decades from 2000 to 2019; however, the more recent results indicate that this was not the case in 2022.

In summary, it appears that in both lakes, the spring temperatures, which are taken during the period of active lake stratification (turnover) are more variable and likely reflect seasonal differences in air temperature. However, by August, the measurements in both lakes show no convincing evidence of lake water warming over the past four decades.

ALGAL GROWTH

Algae are simple, typically small aquatic organisms and range in structure from unicellular (a microscopic single cell) to multicellular. As they produce and grow, they form colonies that appear on the surface or attached to various substrates. Algae are always present in lakes and rivers and are at the base (primary) of most lake food webs, and as such, are critical components of a healthy aquatic environment. Without algae, zooplankton (small animals that feed on algae) would not survive, and this would impact the survival of fish and other animals farther up the food chain.

When conditions are favourable, both benthic and planktonic cyanobacteria as well as other types of algae can increase to levels that result in poor water quality and an algal bloom or scum may form.

Conditions that promote bloom development include:

- sufficiently high levels of nutrients in either sediments or water (primarily phosphorus and to a lesser extent nitrogen), as some species can manufacture their own nitrogen from the atmosphere);
- calm weather conditions and shallow water with low water flow;
- strong sunlight; and,
- high air and surface water temperatures

Nutrient enrichment and phosphorus in particular has been associated with increases in algal biomass in freshwater systems worldwide. Recent studies indicate that climate change is a potent catalyst for the further expansion of algal blooms because of the warming of surface waters, longer periods of open water (fewer ice covered days) and more intense rainfall which can flush soil-borne nutrients into near-shore waters. Rising air and water temperatures favour most bloom-forming planktonic blue-green cyanobacteria because they have higher temperature requirements and because they are able to regulate their buoyancy under conditions of reduced vertical water column mixing (lake turnover) which occurs under rising surface water temperatures as the season progresses.

Although algal blooms are the primary focus of concern, the sediment dwelling algae and those that grow on rocks along the shoreline are also of concern. They are aesthetically unpleasant and also make shoreline navigation difficult, due to their slimy and slippery nature. As the season progresses, and they complete their life cycle, they can be dislodged from bottom and shore growing locations and can drift into slow moving water of bays along the shore where they start to decompose. Many on Kakshe Lake have noticed the unpleasant odours that begin to arise in the late summer and fall as this process takes place. These floating mats also can be mistaken for late-season blooms, as they are dislodged and float into shoreline locations. However, on closer examination, they typically appear less vibrant than the colours of algae in an active bloom.

In a 2011 publication (Winter et al., 2011), the Environment Ministry's investigations of algal blooms in Ontario were summarized and their findings confirmed the following trends:

- The total number of algal blooms reported in Ontario increased significantly from 1994 to 2009, and there also were significant increases in the number of blooms dominated by cyanobacteria and chlorophytes.
- Most lakes (50) had a single bloom report, 11 lakes had blooms reported in two years, four lakes had reports in three years, and one lake had reports in eight of the years between 1994 and 2009.
- In 2009, 16 of the 24 blooms reported tested positive for the presence of microcystin, one of several toxic substances which can be released by blue-green algal blooms.
- A significant increase in day of year the last bloom was reported in a given year was observed, indicating that blooms are being detected and reported later in the year compared to 15 years ago. In contrast, no change was seen in day of year the first bloom was reported.

While this Environment Ministry report only covered algal bloom development through 2009, the detection of increasing numbers of harmful blue-green algal blooms has continued to increase, as confirmed by the Simcoe- Muskoka Health Unit in Table 1 below.

Table 1: Blue-Green Algae Impacted Lakes in the Simcoe=Muskoka Area- 2018 through 2022

Year	Blue-Green Algal Bloom Impacted Lakes	Number of Bloom Alerts
2018	Three Mile, St. John, Leonard, Rosseau, Lamont Creek	6
2019	Three Mile, Brandy, Bass*, Echo, St. John, St. George and MacLean	8
2020	Three Mile, Brandy, St. John, Black, Leonard, Simcoe, Bruce, Muskoka, Silver, Stewart, Little, Ten Mile, Otter and Kahshe	18
2021	Georgian Bay, Three Mile, Little, Stewart, Kahshe , Mary, Menaminee, Fawn, Paint, St. John, Leonard and Bass*	12
2022	Fairlain, St. John, Three Mile, St. George, Georgian Bay (Penetang Harbour), Bass*, Mary, Leonard, Simcoe (Smith’s Bay) and Muldrew	10

*another Bass Lake in Township of Muskoka Lakes

Unfortunately, as noted above, harmful blue-green algal blooms have now been confirmed in Kahshe Lake in both 2020 and 2021 but **not in 2022**. In 2020, the bloom was located along the northern shoreline in the Oak Road vicinity and was investigated by staff from the MECP. In 2021, the first report of a bloom was in the east end of the lake (actually in the Kahshe River), but this was followed by reports of similar blooms in several areas of the lake, and as such, the alert was issued to cover the entire lake. Further details on these specific blooms and any others going forward have been described in greater detail in the KLRA Web’s Water Quality portal and can be accessed via this link:

<https://kahshelake.ca/resources/Documents/Lake%20Steward/2022/Current%20Algal%20Bloom%20Status%20for%20Kahshe%20and%20Bass%20Lake-R3%20Feb2022-TCAccepted.pdf>

To further explore the relevance of these harmful algal blooms in lakes in the Muskoka and surrounding areas, the MECP’s 2018 and 2019 LPP total phosphorus data for each of the above algal-impacted lakes were examined and compared to the phosphorus levels in Kahshe and Bass Lakes over the same time period. In cases where there was no LPP data, the total phosphorus levels from the DMM investigations were used. Of the 13 impacted lakes, total phosphorus levels for 10 were found. While it must be noted that the phosphorus levels for the above water bodies in 2018 and 2019 may not accurately reflect the water concentrations at the specific location or time each bloom was detected, they do provide a general picture of the concentrations that were documented in the impacted lakes. In the case of larger lakes, with multiple sampling locations, the water quality sampling sites located closest to the general area where the algal bloom was detected were utilized.

The total phosphorus levels in the 10 lakes with data are shown in Figure 15 below.

Figure 15:

As is apparent from Figure 15 above, three of the impacted lakes (Three Mile, St. John and Brandy) had very high total phosphorus levels, so the presence of an algal bloom in these lakes could not be considered a surprising result. However, five of the impacted lakes (Rosseau, Muskoka, Leonard, Bass and Echo) had total phosphorus levels well below those of both Kahshe and Bass Lakes.

These findings give cause for concern, as this trend towards increasing numbers of late-season harmful algal blooms throughout Muskoka does not appear to be directly associated with increasing levels of total phosphorus or nitrogen compounds determined via these early spring water quality sampling programs from the deep water of mid-lake sampling sites.

This apparent anomaly prompted the development of the KLRA-funded Near Shore Water Sampling Project (NSWSP) in 2021 and the findings from those water sampling activities identified a causal linkage between algal bloom development and water quality parameters indicating the leaching of soil-borne and mobile nitrogen compounds from septic systems or lawns located near the shore which attract large numbers of Canada geese were involved. This appears to be associated with higher intensity rainfall events characteristic of a changing climate which may be accelerating the leaching process. The findings from the NSWSP have been reported and posted on the KLRA’s Water Quality web portal which is accessible via this link:

<https://kahshelake.ca/resources/Documents/Lake%20Steward/2022/FULLNSWSP-RevNov-2022-FinalwCoA.pdf>

The NSWSP findings are briefly summarized below:

- Mid-lake, deep water sampling in the spring of the year is a reasonable way to track long-term, historical changes in water quality but is not providing a biologically relevant assessment of water quality in the near-shore environment where HABs have been documented.
- The mid-lake, deep water sampling also has failed to capture much higher total phosphorus levels in the east end of the lake, as there are no DMM sampling sites in that area.

- Levels of algal-friendly nutrients (phosphorus and nitrogen) in the near-shore environment are almost always higher than in the mid-lake and tend to fluctuate as the season progresses, further limiting the relevance of the spring sampling of mid-lake sites in terms of assessing the potential for HAB development.
- The near-shore water chemistry for some algal-friendly nutrients appear to be associated with effluents from human & animal waste sources and are known to be linked with HABs.
- Although more study is warranted, the near-shore findings point to accelerated leaching and/or runoff of soil-borne nutrients due to a changing climate which is resulting in more intense rainfall events.

To demonstrate some of the above NSWSP findings, Figure 4A from the near-shore project has been reproduced here as Figure 16, and shows how total phosphorus levels in the near-shore environment compared to those from the historical DMM and MECP mid-lake, deep water monitoring locations.

Figure 16:

Although we have virtually no control over the change that is affecting our climate, there are very definitely actions we can and must take to minimize the accelerated leaching of algal friendly nutrients to our shoreline water and thereby reduce the potential for future algal blooms. These actions have been thoroughly explored by the Conservation Committee and are summarized below:

- 1. Divert roof drainage and runoff from paths and other hard surfaces away from your septic system and the shoreline. If necessary, direct rain water into rock-filled drainage pits.**
- 2. Keep most of your shoreline as natural as possible with a zone of trees, shrubs or tall grass between the shore and any lawn area to discourage grazing by Canada geese and to reduce soil & goose poop runoff into the lake.**
- 3. Have a licensed professional pump out and inspect your septic system for failures and deficiencies every 3-5 years and more often for aging systems installed pre-2000. The Town will be inspecting**

in 2023, but we don't need to wait until then and be subject to system shutdown until failing systems are repaired.

4. Don't use phosphorus or nitrogen fertilizers or cleaning agents anywhere near the shore.

4.2 Calcium Depletion

Another chemical of potential concern to the health of our lake is calcium. In this case, the concern is not related to shoreline development, but arises from a Muskoka trend towards decreasing levels of calcium which has been documented in a recent Canada Water Network Research Program in the Muskoka watershed. Why is calcium so important?

Calcium is a nutrient that is required by all living organisms, including very small organisms called zooplankton that live in the waters of Muskoka lakes and are a key component of the lower component of the food chain for other aquatic and terrestrial organisms higher up the food chain. The reproduction of these organisms as well as others like mollusks, clams, amphipods and crayfish have been shown to be adversely affected by low levels of calcium in lake waters.

Based on data from over 700 lakes in Ontario, about 35% currently have calcium levels below 1.5 mg/L, which is considered a limiting threshold for the survival of zooplankton species like *Daphnia* that comprise a major component of the aquatic food chain. Other species require more than 1.5 mg/L while some can tolerate levels as low as 0.5 mg/L. One of the implications of reduced calcium is a lowering of biodiversity. Dr. N. Yan explained how this can happen using calcium as an example in response to a Toronto Star article in 2014. He elaborated on a study designed to highlight a fairly fundamental shift from crusty to jelly-clad species as dominants in the zooplankton, as we move from a higher calcium, phosphorus world in our lakes to a lower calcium, lower phosphorus world.

This has resulted in *Holopedium* taking dominance over *Daphnia*, as it needs 20 times less calcium, and two times less phosphorus than *Daphnia*. It also survives attacks from invertebrate predators better and was already widespread in our lakes. As such, *Holopedium* have become more dominant over the last 20-30 years at the expense of more calcium-needy competitors.

There are a few possible ecological concerns of the change. Yan explained:

- 1) We are losing biodiversity here, as several species of *Daphnia* are losing out to only one *Holopedium* species;
- 2) The nutritional value of the large animal plankton is reduced, as *Holopedium* has a much lower mineral content than *Daphnia*. The implications of this should be explored, but are not yet known; and,
- 3) There may well be less food passed up the food chain to fish in our small lakes where invertebrate predators are actually key steps between plankton and fish, because *Holopedium* is pretty well protected from most invertebrate predators by its jelly coat. When it is eaten, it has lower mineral content.

In our Muskoka lakes, the absolute abundance of *Holopedium* has increased by an average of about two fold over the last 20 years, and the relative abundance has increased more, said Yan, while the abundance of five species of *Daphnia* has declined. There are two other, smaller species of *Daphnia* that need less calcium than their congeners, and they are still doing well, but this won't last if calcium continues to fall, he said.

Still, jellification doesn't mean the end to fish in our lakes. The thing to understand, said Yan, is that "the sky is not falling, but it's not quite the same sky as it once was." No doubt ongoing research and monitoring is critical to the health of our lakes. The upside to the attention raised by The Toronto Star's article this week, said Yan is that it highlights how "research in Muskoka is alerting the world to intriguing and fundamental changes that accompany human interventions in the natural world."

Studies have shown that the gradual reduction in calcium levels in watershed soils and the water of lakes and rivers is associated with acidic rainfall, forest harvesting and climate change. In the early days, very acidic rain leached the calcium from soils faster than it could be regenerated via natural weathering of underlying rocks and this resulted in increased levels in the water of some lakes. However, as acid deposition rates were reduced, less calcium is now being leached from watershed soils into lakes, resulting in lower calcium concentrations that are threatening the health of aquatic species. Forest harvesting also has played a role, as the removal of timber and subsequent re-growth of forests following timber harvesting has further diminished the supply of calcium in soils that is available for leaching to lakes. Finally, climate change is also playing a role, as it has in some areas, resulted in decreased water flow within the watershed, resulting in less calcium being exported from watersheds to lakes.

Fortunately, the DMM water sampling program has included calcium since 2004, while the MECP have been analyzing Kahshe Lake water for calcium since 2008. Figure 17 below shows the DMM Calcium levels for the period from 2004 through 2022.

Figure 17:

These analytical findings demonstrate that there has been no major decline in calcium concentrations in either Kahshe or Bass Lakes over this 18 year monitoring interval. While the concern with calcium is lower levels, this chart also demonstrates that there is no concern in either lake from a toxicity perspective.

Figure 18 that follows plots the calcium data for Kahshe Lake by the two sampling programs (DMM and LPP) over this same time period. It also shows the lower limit threshold of 1.5 mg/L which has been recognized as a level below which the survival of sensitive species such as *Daphnia* may be impacted.

Figure 18:

Based on this information, it can be concluded that:

- Calcium concentrations in Kahshe Lake are well above the lower limit that has been set to protect some sensitive zooplankton species. Although not shown on this chart, the calcium levels in Bass Lake also are well above the threshold to protect sensitive zooplankton species.
- Although we don't have an extensive history of calcium monitoring results, the data we do have show no obvious signs of increasing or decreasing concentrations.
- While the calcium results look favourable, there was a population explosion of *Holopedium sp.* in Kahshe Lake late in both 2021 and 2022; although these jelly-like orbs were a nuisance in the water for swimmers, it is not known if this represents a concern ecologically further up the aquatic food chain.

4.3 Lake Acidification

Water acidity is measured on a unitless scale referred to as pH. The pH of water is a measure of the hydrogen ion concentration expressed on a scale of 0 to 14, with a pH of 7 being neutral, values below 7 being acidic and above 7 being alkaline. As the hydrogen ion concentration is measured on a logarithmic scale, the change in pH of 1 unit (i.e. from 7.0 to 6.0) represents a 10-fold increase in acidity. Distilled water is considered to be neither acidic nor alkaline, and has a pH of 7.0. However, even in the absence of any man-made acidic gases, the natural levels of carbon dioxide in the atmosphere will react with water to generate carbonic acid, and this will cause rain to have a natural pH of about 5.6.

Although source-oriented acid gasses and particulates have contributed significantly to the acidification of lakes in Ontario, particularly around major sulphur sources in the Sudbury basin, there has been noticeable recovery over the last two decades as emission controls were implemented. The ingress of acidic gasses and particulates of nitrogen and sulphur from transboundary air flows into southern Ontario also have been reduced.

The Provincial water quality objective is to keep pH between 6.5 and 8.5, as values above or below those levels can be harmful to some aquatic organisms.

In the green-shaded figure to the left, the pH level at which key organisms may be lost as their environment becomes more acidic has been shown (EPA. 2017; Effects of Acidification on Ecosystems). Some types of plants and animals are able to tolerate acidic waters and moderate amounts of aluminum. Others, however, are acid-sensitive and will be lost as the pH becomes more acidic. Generally, the young of most species are more sensitive to environmental conditions than adults. At pH 5, most fish eggs cannot hatch. At lower pH levels, some adult fish die. Some acidic lakes have no fish. Even if a species of fish or animal can tolerate moderately acidic water, the animals or plants it eats might not. For example, frogs have a critical pH around 4, but the mayflies they eat are more sensitive and may not survive pH below 5.5.

The chart below in Figure 19 shows the pH values for Kahshe and Bass Lakes from 2004 through 2019.

Figure 19:

It is apparent from Figure 19 that the pH of Kahshe and Bass Lakes is:

- At or slightly above the lower end of the optimum pH range of 6.5-8.5, which is good.
- Above the level of 6.0 where impacts to some sensitive aquatic species might be encountered (see EPA species sensitivity picture above), which also is good news.
- Not showing any evidence of either an increase or decrease in acidity over the 18 year period of monitoring.

While the pH findings represents good news, it should also be recognized that the waters of Kahshe and Bass Lakes have low levels of alkalinity, and as such, are more susceptible to acidification, as the ability of the water to buffer (neutralize) incoming acid via precipitation is low.

4.4 Metals and Other Chemical Contamination

The DMM has analyzed water samples for a much larger suite of chemical parameters than those that are routinely reported in their year-end report and data sheet summaries. This leaves a large number of chemicals that have been analyzed but which have not been specifically evaluated in terms of their potential impacts on aquatic species.

The full suite of chemicals analyzed via the DMM sampling program in 2022 included: chloride, nitrogen (ammonia + ammonium), nitrogen (nitrite+nitrate), total nitrogen, sulphate, aluminum, barium, beryllium, cadmium, calcium, chromium, cobalt, copper, iron, lead, magnesium, manganese, nickel, potassium, silicon, sodium, strontium, titanium, vanadium, zinc. In addition, the following additional parameters were added to the suite of chemicals in 2012 and repeated annually since then: antimony, arsenic, boron, selenium, silver, thallium and uranium.

As some of these parameters have not been included in the DMM summary table of additional chemical parameters, this report attempts to do this by comparing the results for all years for which data exist to surface water benchmarks that are available from the MECP or other regulatory agencies. A brief description of the benchmarks which have been used and what they're designed to protect follows:

- For the anions and cations and other parameters included in the DMM dataset, the findings have been compared to currently available aquatic protection values (APVs) used by the Ontario MECP (MOE, 2011). These values represent the highest concentration of a contaminant in surface water to which an aquatic community can be exposed indefinitely without resulting in an adverse impact.
- In cases where an MECP APV was not available, a similar format to the one used by the MECP in protecting surface water from ground water discharges associated with contaminated sites (*O. Reg. 153/04* as amended) has been followed. This involved first checking for a U.S. EPA chronic ambient water quality criterion (based on a continuous chronic criterion, (U.S. EPA, 2012; U.S. EPA, 1986));
- If neither of these sources had a value, a Canadian Water Quality Guideline (CCME, 2012), a B.C. Ambient Water Quality Criterion (B.C. 2000; B.C. 2001a and b) or a U.S. EPA Tier-II Secondary Chronic Value (Suter II and Tsao, 1996) has been used.

In all cases, the surface water protection provided via these benchmarks is for long term exposure to concentrations that are considered chronic, as opposed to short-term protection against acute effects.

The charts for all chemicals along with their respective water quality benchmarks have been attached as Attachment 2 and a summary of the findings has been presented in Table 2 below.

Table 2: Summary of Chemical Analysis Results – Kahshe and Bass Lake – 2022

Category	Analyzed Parameter	Evaluation Benchmark ¹	Comments
Anions	Chloride	MECP APV	All reported values well below aquatic benchmark and chloride concentrations in Bass Lake are marginally higher than those in Kahshe. Note that the chart uses a logarithmic scale.
	Nitrogen (Ammonia + Ammonium)	BC Water Quality Guideline	All reported values well below aquatic benchmark and concentrations in Bass Lake are slightly higher than those in Kahshe. Note that the chart uses a logarithmic scale. The impact of ammonium nitrogen also is important as an algal friendly nutrient, and this has been discussed in Section 4.1 of the report.

Category	Analyzed Parameter	Evaluation Benchmark ¹	Comments
	Nitrogen (Nitrite + Nitrate)	Canadian Water Quality Guideline	All reported values well below aquatic benchmark and concentrations in Kahshe are slightly higher than those in Bass. Note that the chart uses a logarithmic scale. The impact of nitrate nitrogen also is important as an algal friendly nutrient, and this is discussed in Section 4.1 of the report.
	Total Nitrogen	None Found	Total nitrogen (organic + inorganic) concentrations from 2004 to 2019 were calculated by adding measured total Kjeldahl nitrogen (which consists of organic nitrogen and ammonia+ammonium nitrogen) and measured nitrate+nitrite nitrogen. This was discontinued in 2021, as the laboratory now reports its findings for total nitrogen as a measured value. The impact of nitrogen also is important as an algal friendly nutrient, and this is discussed in Section 4.1 of the report. Also it is interesting to note that total nitrogen is higher in Bass L while nitrate+nitrite nitrogen is noticeably lower in Bass vs. Kahshe.
	Sulphate	BC WQC	All reported values well below benchmark and no trend is apparent.
Cations	Aluminum	Interim Canadian WQG	All reported values for Kahshe Lake well below the WQG for aluminum. In contrast, Bass Lake values are higher than those from Kahshe Lake and most are close to or marginally above the upper range in the WQG. Note that the CWQG for aluminum is both pH and DOC dependent. As such, the low end of the range of CWQGs based on the pH and DOC levels has been plotted.
	Barium	MECP APV	All reported values well below benchmark. Note that the chart uses a logarithmic scale.
	Beryllium	MECP APV	All reported values well below benchmark.
	Cadmium	MECP APV	The Aquatic Protection Value is exceeded in 2018, 2019, 2021 and 2022 as well as in two earlier years. The early exceedances are likely a sampling (water filtering) or laboratory quality control issue, as the APV is very close to the detection levels of most laboratories. Similarly, the apparent increase in the more recent results is due to a change in the Laboratory DL values which now exceed the APV. This issue is further apparent in 2021 and 2022, as the laboratory increased its DL by 2-fold. As such, the reported exceedances are not measured concentrations, simply the level of detection by the laboratory.
	Chromium	MECP APV	All reported values well below benchmark and in 2021 and 2022, the laboratory DL increased by 2-fold. As such the apparent increase in Cr concentration is simply a laboratory artifact.
	Cobalt	MECP APV	All reported values well below benchmark. However, as for Cr, the Co DL increased 10-fold in 2021 and 2022, and as such the apparent increase in Co concentration is simply a laboratory artifact.
	Copper	MECP APV	As for Co, the DL for Cu increased 10-fold in 2021 and 2022, and as such, the apparent increase in Cu concentration is simply a laboratory artifact.
	Iron	U.S. EPA CCC	All reported values for both lakes are well below benchmark, although the 2022 results for Bass Lake continue the trend of being about 2-times higher than in Kahshe Lake.

Category	Analyzed Parameter	Evaluation Benchmark ¹	Comments
	Lead	MECP APV	The DL in 2021 and 2022 has increased more than 2-fold, so the apparent increase is simply a laboratory artifact. Note that the chart uses a logarithmic scale.
	Magnesium	U.S. EPA LCV	All reported values are well below benchmark. For some reason, Mg not analyzed in 2021, but was in 2022. Note that the chart uses a logarithmic scale.
	Manganese	BC AWQC	All reported values well below aquatic benchmark and as for iron and aluminum, manganese concentrations in Bass Lake are noticeably higher than those in Kahshe.
	Molybdenum	MECP APV	All reported values well below benchmark. In 2021 and 2022, the laboratory DL increased by 2-fold. As such the apparent increase in Mo concentration is simply a laboratory artifact. Note that the chart uses a logarithmic scale.
	Nickel	MECP APV	All reported values well below benchmark and as for others, DL increased by 10-fold, so as in 2021, the apparent increase in 2022 is a laboratory artifact.
	Potassium	U.S. EPA LCV	All reported values well below benchmark. Note that the chart uses a logarithmic scale.
	Silicon	None Found	In most years, including 2021 and 2022, silicon (reactive silicate) concentrations in Kahshe Lake are noticeably higher than those in Bass Lake. No aquatic protection benchmark was found for comparison.
	Sodium	MECP APV	All reported values well below aquatic benchmark and concentrations in Bass Lake are slightly higher than those in Kahshe. Note that the chart uses a logarithmic scale.
	Strontium	U.S. EPA T-II SCV	All reported values well below benchmark. Note that the chart uses a logarithmic scale.
	Titanium	None Found	In most years up to and including 2019, titanium concentrations in Bass Lake were noticeably higher than those in Kahshe Lake as was the case for aluminum, iron and manganese. An increase in the DL in 2021 and 2022 masks this difference as all values were reported as DLs. No aquatic protection benchmark was found for comparison.
	Vanadium	MECP APV	All reported values well below benchmark and a 2-fold increase in the DL masks any interpretation of the 2021 and 2022 values.
	Zinc	MECP APV	All reported values well below benchmark.
Other Chemicals	Dissolved Organic Carbon	DMM Notes	Although there is no aquatic benchmark, the findings for Bass Lake are noticeably higher than those in Kahshe and also are at or slightly higher than 7 mg/L, which is the Ontario aesthetic objective for recreational use.
	Electrical Conductivity	None Found	In most years including 2022, EC levels in Bass Lake are slightly higher than those in Kahshe Lake. No aquatic protection benchmark was found for comparison.
	Alkalinity	DMM Notes	Although there is no aquatic protection benchmark, the alkalinity of both Kahshe and Bass Lakes (generally higher in Bass L) is below 10 mg/L, indicating that both lakes have low buffering capacity and therefore are potentially susceptible to acidification.

Category	Analyzed Parameter	Evaluation Benchmark ¹	Comments
Recently Added Cations	Antimony	MECP APV	All reported values well below benchmark and as for several other parameters, the DL increased in 2021 and 2022 masking any comparison of the levels in both lakes. Note that the chart uses a logarithmic scale.
	Arsenic	MECP APV	All reported values well below benchmark and as for several other parameters, the DL increased in 2021 and 2022 masking any comparison of the levels in both lakes. Note that the chart uses a logarithmic scale.
	Boron	MECP APV	All reported values well below benchmark and as for several other parameters, the DL increased in 2021 and 2022 masking any comparison of the levels in both lakes. Note that the chart uses a logarithmic scale.
	Selenium	MECP APV	All reported values well below benchmark and as for several other parameters, the DL increased in 2021 and 2022 masking any comparison of the levels in both lakes. Note that the chart uses a logarithmic scale.
	Silver	MECP APV	Historically, silver has never been detected as all values dating back to 2004 have been less than the DL. In 2021 and 2022, the DL increased 5-fold, masking any comparison of the data between the two lakes. As the DL now exceeds the APV, the potential impact of this parameter cannot be determined. Note that the chart uses a logarithmic scale.
	Thallium	MECP APV	Historically, thallium has never been detected as all values dating back to 2004 have been less than the DL. In 2021 and 2022, the DL increased 5-fold, masking any comparison of the data between the two lakes. Note that the chart uses a logarithmic scale.
	Uranium	MECP APV	Historically, uranium has never been detected as all values dating back to 2004 have been less than the DL. In 2021 and 2022, the DL increased 2-fold, masking any comparison of the data between the two lakes. All DL values are well below benchmark. Note that the chart uses a logarithmic scale.
Legend: ¹ Evaluation Benchmarks <ul style="list-style-type: none"> ▪ MECP APV means Ontario Ministry of Environment, Conservation and Parks – Aquatic Protection Value ▪ EC CWQG means Environment Canada – Canadian Water Quality Guideline ▪ BC AWQC means British Columbia Ambient Water Quality Criterion ▪ U.S. EPA CCCC means United States Environmental Protection Agency Continuous Chronic Criterion ▪ U.S. EPA LCV means United States Environmental Protection Agency Lowest Chronic Value ▪ U.S. EPA Tier II SCV means United States Environmental Protection Agency Secondary Chronic Value 			

Although the main goal of the above discussion was to examine the potential of these parameters to impact water quality in terms of aquatic health, the comparison also identified a number of cases where concentrations in Kabshe or Bass Lake were higher in one than in the other. While the cause of this finding is not immediately apparent, it is interesting given the finding of noticeably higher concentrations of total phosphorus in Bass Lake compared to Kabshe Lake. To explore this further, Table 3 below identifies the parameters which are either slightly or noticeably elevated in one lake compared to the other. The increase in the laboratory DL for several parameters in 2021 and 2022 has masked this

type of comparison for titanium, but the DL increase did not affect the intra lake comparison for any others.

Table 3: Comparison of Chemical Parameters in Kahshe vs Bass Lakes - 2022

Bass Lake Concentrations Higher than in Kahshe		Kahshe Lake Concentrations Higher than in Bass	
Noticeably	Slightly	Noticeably	Slightly
<ul style="list-style-type: none"> ▪ Total N ▪ Al ▪ Fe ▪ Mn ▪ Ti (masked in 2021 by DL increase) ▪ DOC ▪ Alkalinity 	<ul style="list-style-type: none"> ▪ Cl ▪ N-NH₄ ▪ Ca ▪ Na ▪ EC 	<ul style="list-style-type: none"> ▪ Si ▪ N-NO₃ 	<ul style="list-style-type: none"> ▪ None

As noted above, the reason for these water quality differences remains unknown. However, they may play a role in the search for causality in the elevated total phosphorus levels in Bass vs. Kahshe Lake.

4.5 Dissolved Oxygen Depletion

Dissolved oxygen (DO) in lake water is important for two main reasons: 1) it is essential for the survival of all aquatic organisms, and 2) a lack of oxygen in the lower layers of the lake (referred to as being anoxic) can cause mobilization of phosphorus from sediments. This is referred to as internal phosphorus loading.

In addition to the consumption of oxygen by fish and other aquatic organisms, the decomposition of organic matter in all layers of the lake consumes oxygen. However, because of the thermal stratification of lake water during the ice-free period, only the upper layers of water are replenished with oxygen as a result of photosynthesis by aquatic plants, in-bound water from streams and atmospheric oxygen as a result of mixing caused by wind and waves. As such, the gradual depletion of oxygen in the lower layers (hypolimnion) of the lake progresses following spring turnover and these lower waters do not get re-oxygenated until the late fall turnover again takes place.

Water temperature also plays a role in the dissolved oxygen cycling process, as warm water becomes saturated at lower concentrations than required for cold water – i.e. warm water is able to hold less DO in solution. However, the bottom line is that the colder waters near the bottom of the lake become gradually depleted of oxygen over the ice-free period and can reach levels that will not support aquatic species.

The setting of an aquatic benchmark for DO is typically conducted under both an acute (short term, high concentration) and a chronic (long term, lower concentrations) basis. For chronic exposure, aquatic organism effects include the traditional growth and reproduction impairment, swimming impairment and long term impacts on survival. The low oxygen threshold at which some reaction first becomes apparent is usually referred to as the incipient or critical level. At this level, the organism must extend or adjust its available energies to counteract the influence of hypoxia (oxygen starvation) and/or to move to waters with higher DO levels. Unfortunately, the variability in toxicity symptoms and exposure times

challenges the derivation of water quality guidelines for DO, and as a result, the guideline derivation does not follow the standard process.

For warm water lakes like Kahshe and Bass, the Provincial Water Quality Objective (PWQO) and the Canadian Water Quality Guideline (CWQG) are set at 5 and 5.5 mg DO/L, respectively. This report will use the lower of the two, as some other agencies have set DO benchmarks in the 3-4 mg/L range.

To examine the DMM findings for DO, the data have been averaged in a manner similar to what was done with water temperatures. This generated a mean for the 1980s&1990s, 2000-2009 and 2010-2019 for all Spring and Summer sampling up to 2022, and these findings for Kahshe Lake are plotted below in Figures 20 and 21.

Figure 20:

Figure 21:

The above two charts for Kahshe Lake have been summarized below:

- As expected, the DO levels in the Spring sampling event reveal only a slight trend of decreasing DO levels with increasing water depth, and in all cases the DO levels are well above the aquatic health-based PWQO. These findings are consistent with lake water turnover that vertically mixes the water across the depth of the lake commencing when the ice cover period ends in April.
- However, by early August, the 2022 DO levels are considerably higher than in previous years/decades down to around 5-6m depth and then level off or rise slightly with increasing depth down to 20m.
- More importantly from an aquatic health perspective, the DO levels from 2022 appear to follow the historical trend of falling below the PWQO at a depth of around 5m but do depart from the continued decline in DO with increasing depth observed in the 1980s and 1990s period by gradually recovering (increasing) in 2022, following the trend that was observed in the 2000-2009 and 2010-2019 decades. As such, while the findings of DO levels below the aquatic benchmark are of concern, the trend towards gradually increasing levels at depths below around 6m that has been happening after the 1980s and 1990s is good news.

The DO levels in Bass Lake for both Spring and Summer sampling times are charted below in Figures 22 and 23.

Figure 22:

Figure 23:

The above two charts for Bass Lake have been summarized below:

- As for Kahshe Lake, the DO levels in the spring sampling event reveal only a slight trend to decreasing DO levels with increasing water depth, and in all but the lowest depths, the DO levels are well above the aquatic health-based PWQO. These findings are consistent with lake water turnover that vertically mixes the water across the depth of the lake, although to a lesser extent in Bass Lake due to its more shallow depth.
- However, by early August, the 2022 DO levels are essentially similar to the two historical records of DO levels down to about 2m depth and then decrease gradually through the 3m depth, falling below the PWQO just below the 2m depth.
- More importantly from a biological perspective, unlike Kahshe Lake, there appears to be a trend towards DO levels falling below the PWQO at more shallow depths (just below 2m) than back in the 1980s and 1990s when DO crossed below the PWQO at depths almost at lake bottom (just below 3m).

4.6 Benthic Health

Monitoring of bottom-dwelling aquatic invertebrate communities which live within the sediment or 'bottom mud' has been carried out at three locations on Kahshe Lake by the DMM since 2003. However, benthic monitoring on Kahshe Lake was suspended in 2016 in order to focus more on Bass Lake due to its classification as a 'Transitional' lake requiring additional assessment due to its elevated total phosphorus levels.

As both lakes were declared 'Vulnerable' in 2020 due to either total phosphorus above 20 µg/L or the documented presence of a harmful algal bloom, benthic monitoring was again undertaken in 2021 and 2022 and will be conducted annually until the completion of planned Causation Studies by the DMM.

The findings from the 2022 benthic sampling and counting survey which was undertaken at Site B2 on August 23, 2022 are presented below. This activity could not have been undertaken without the support of the following Kahshe Lake volunteers who carried out the count under the supervision of Ms Jess Lario, the Biotechnician from the DMM:

- Greig and Sue Holder
- Barb and Brian Riley
- Wes Treleven
- Matty Grossman
- Gail Pearson
- Ben Pearson
- Izzy Pearson

Following the counting and identification, the DMM biotechnician worked up the benthos identification summary and the organisms were broken into families of benthos as has been the case since monitoring began. The tabular summary is presented below.

Aquatic Invertebrate Data Sheet

Hilsenholt Index	7.23			6.62			6.77			6.69	5.93		6.25	

* The Muskoka Average is based on 200 samples collected at 82 reference sites between 2007 and 2016. Reference sites from 11 mesotrophic, 1 eutrophic and 29 oligotrophic lakes throughout Muskoka were used.

In her summary, the following three features of the 2022 findings at Site 2 included:

- % EOT (the good sensitive bugs has drastically increased comparatively to past years;
- %&Chir (the more tolerant species) is nearly at 0; and,
- HBI also decreased and with this value, the lower the better

These data along with the findings from previous benthic monitoring at Sites 2, 3 and 6 have been charted in Figure 24 below. As this year's report from the DMM was not as comprehensive as the 2021 report, some general information on the reasoning for the evaluation of benthic growth as well as some clarification on what the various families represent has been extracted from the 2021 report and shown in green shaded text below:

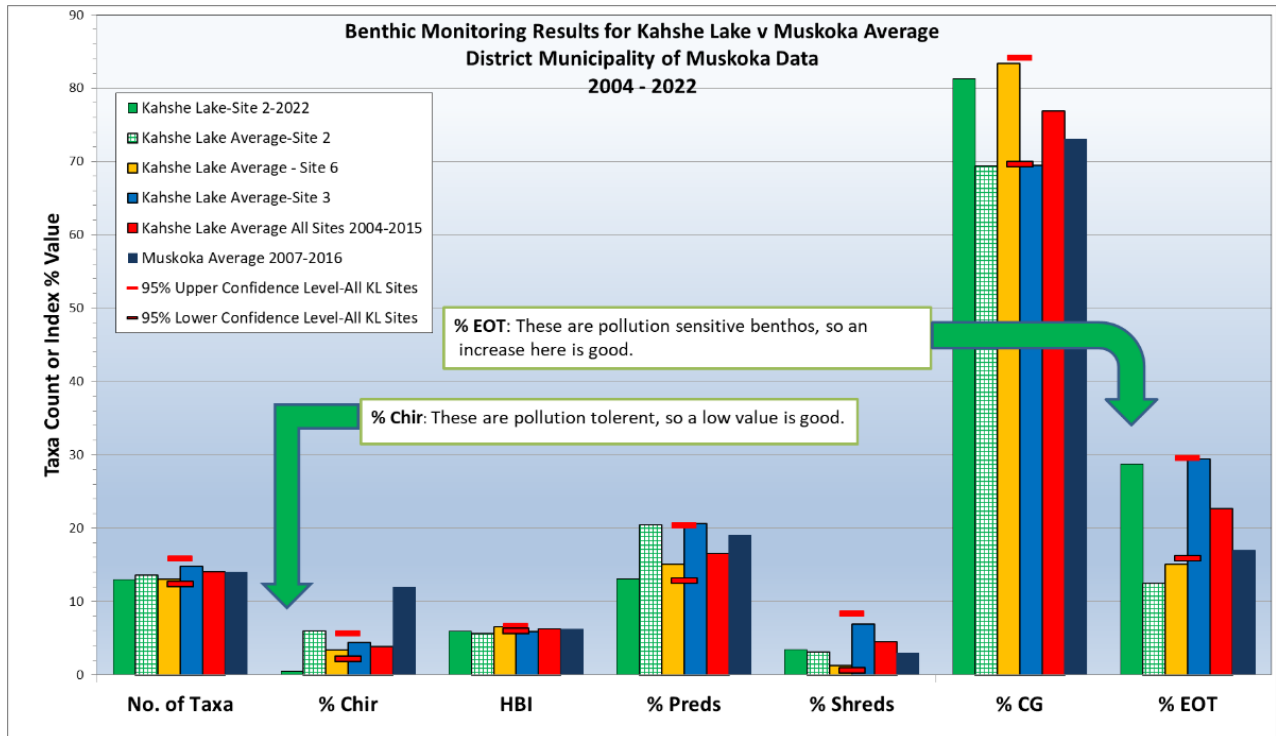

Each year we sample our established sites to determine which benthic macroinvertebrates are found. These benthos indicate the health of the riparian zone (section between shallow water and dry land) and the littoral zone (shallow water nearest to dry land). These two zones are especially important to lake health as they are impacted by snowmelt, runoff, sedimentation, etc.

Collected benthos are grouped into seven (7) different categories, in which three (3) are mainly focused on: EOT, Chironimids, and Richness. The % EOT includes mayflies, dragonflies, and caddisflies, which are benthic macroinvertebrates who are **intolerant** to pollution. % Chironimids is focused on the invertebrate named a Midge (or blood worm) which are **tolerant** to pollution and can survive in harsh environments. Richness is the biodiversity of species found within the sample, and with biodiversity, the more the better. The other four (4) categories are more used as reference, in that if one year a number drastically jumps or falls, further investigation might be required.

With these numbers alongside the Muskoka Average*, we are able to understand the direction the lake is heading in regards to shoreline and lake health. If the % EOT (intolerant) is low, and % Chironimids (tolerant) is high, this indicates that the environment may not be suitable for the intolerant benthic invertebrates. This indicates to us that this section of the lake may be impacted by sources such as development, runoff, or other anthropogenic sources.

As noted above, Figure 24 displays the full benthic monitoring results for Sites 2, 3 and 6 for the period from 2004 to 2022 as well as the Muskoka average from 82 reference sites over the period from 2007 to 2016.

Figure 24:

In addition to the three main findings for 2022 identified above, this figure also demonstrates that the benthic community on Kahshe Lake is comparable to the Muskoka average for most benthic groupings, with the exception of % Chir and % EOT, where lower and higher benthic counts respectively are desirable outcomes.

A few pictures of the benthic counting in 2022 follow:

5.0 Summary of the Six Lake Health Parameters

In an effort to simplify the reporting of a large amount of measurement and analysis data, the report has been structured to address the following issues/areas of potential concern for both Kahshe and Bass Lakes:

- Nutrients, Water Clarity, Temperature and Algal Growth
- Calcium Depletion
- Lake Acidification
- Metals and Other Chemical Contamination
- Dissolved Oxygen Depletion
- Benthic Health

Facilitate a better understanding of the main findings from each of the six water quality parameters that were investigated, the following blue-shaded text captures the findings from each of those six areas of potential concern.

Climatic Factors and Ice Condition Summary

Air temperatures in 2022 were generally similar to the three previous years and to the 30 year normal for most months, with the exception of much warmer conditions in May and to a lesser extent, August and September. In the case of precipitation, total monthly amounts were noticeably lower in May through July and above normal in August. The lower levels of precipitation in late summer in 2022 may have played a role in the absence of a blue-green algal bloom in 2022 as major late-season precipitation events in 2020 and 2021 appeared to have accelerated the leaching and run-off of algal-friendly nutrients into near-shore waters and the development of harmful algal blooms.

In 2022, the ice-out date was April 16 and the data for Kahshe Lake appear to generally follow the ice-out dates for the larger Muskoka Lakes, with no evidence of a trend towards earlier or later ice-out times on Kahshe Lake over this 135 years period.

Nutrients, Water Clarity, Temperature and Algal Growth Summary

Phosphorus has long been identified as the main concern in terms of water quality and shoreline management due to its major role in algal growth and bloom development. However, more recently, nitrogen also has been identified as a key factor in algal bloom development and it too enters the lake from sources similar to those for phosphorus.

A summary of the findings for the three major algal bloom development variables and for water clarity that have been evaluated is presented below:

PHOSPHORUS

- In both lakes, there has been no long term trend in total phosphorus concentrations over the past 40 years; however, unlike Bass Lake, commencing in 2017, there has been a very gradual increase in total phosphorus in Kahshe Lake with the 2022 levels now well above 'Background' and at the 'Threshold' level of 14.2 µg/L.
- Historically, the total phosphorus levels in Bass Lake are about twice as high as those in Kahshe Lake, with levels of total phosphorus falling marginally above or below the 'Background' level of 20.6 µg/L.
- While there is no clear reason for the gradual increase in total phosphorus in Kahshe Lake over the past few years, this is likely associated with increased current flow from Bass into Kahshe, as it was clearly demonstrated in the 2021 Near-Shore sampling program, that total phosphorus levels are higher in the eastern areas of Kahshe close to the inflow from Bass Lake via the Kahshe River and decline with increasing distance to the west from Bass Lake. A similar trend of increasing iron concentrations in Kahshe during this time period supports this rationale, as like phosphorus, iron levels in Bass Lake are historically higher in Bass Lake than in Kahshe Lake.
- A comparison of the total phosphorus concentrations determined via the DMM and MECP sampling programs have yielded very similar findings, with most of the differences in phosphorus likely due to different spring sampling dates which would be influenced by the degree of lake stratification (turnover).

- While the mid-lake, deep water sampling sites on Kahshe Lake generate an excellent historical record of total phosphorus concentrations for trend analysis, the findings of the 2021 KLRA-funded Near Shore Water Sampling Project demonstrated two important weaknesses in this historical record:
 - it fails to capture higher total phosphorus concentrations at the East end of the lake which has not been sampled via the DMM program; and
 - the mid-lake levels are not representative of the higher and more variable near-shore total phosphorus levels where algal blooms have been identified.

NITROGEN

While recognition of the role of nitrogen in nutrient enrichment and algal growth has not been a focus for as long as phosphorus, there is a growing attention on this nutrient now based on a strong weight of published evidence for its role in promoting algal growth. In water, nitrogen occurs in several different dissolved forms and these factor into the growth of algae and cyanobacteria in different ways.

Ammonium is the easiest nitrogen form for primary producers to acquire and transport into the cell. Nitrate and nitrite ($\text{NO}_3^- / \text{NO}_2^-$) must be actively transported into the cell and then converted to ammonium, which, in turn, requires energy and micronutrients, such as iron. For these reasons, the monitoring has focussed on the two main forms of nitrogen (Ammonia + Ammonium) and (Nitrite + Nitrate). The 2022 findings are summarized below:

- No evidence of a concentration trend in either of the two analyzed forms of nitrogen has been detected in Bass or Kahshe Lakes over the years dating back to 2004.
- In contrast to total phosphorus, the concentrations of nitrate + nitrite in Bass Lake are generally lower than the corresponding analysis results for Kahshe Lake; and as noted in Figure 8 below, this is not the case for total nitrogen, where levels in Bass Lake are always higher than in Kahshe Lake.
- In all cases, the reported nitrogen concentrations are well below any aquatic benchmarks that have been set to protect sensitive aquatic species.
- No algal growth benchmarks for either form of nitrogen have been located, as the linkage between phosphorus, nitrogen and water temperature is too complex to set individual nutrient benchmarks.
- As for total phosphorus, the findings from the KLRA-funded Near-Shore Water Sampling Project conducted in 2021 demonstrate that nitrogen concentrations in the near-shore environment are often considerably higher than these spring-sampled mid-lake levels, often increase or decrease as the season progresses and have likely contributed to the harmful blue-green algal bloom that was documented in 2021. This is discussed in greater detail in the 'Algal Growth' section.

WATER TEMPERATURE

While nutrient enrichment is important, it is not the only factor involved in the promotion of harmful algal growth. Blue-green algae thrive in areas where the water is shallow, slow moving and warm. Water temperature is also important for other reasons, including:

- It affects the solubility of oxygen in water.
- It affects the metabolic rates, life cycles and the sensitivity of all aquatic organisms to parasites and disease.
- It factors into the classification of a lake as a cold or warm water body (both Kahshe and Bass are considered warm water lakes)

The 2022 findings for Kahshe and Bass Lakes are summarized below:

- Water temperature in the spring of 2022 in Kahshe Lake was noticeably warmer down to a depth of 5m and slightly cooler than temperatures recorded at depths from 5 to 10m in all previous averaging periods; below 10m, the 2022 results were similar to those in the past.
- By August 2022, the temperature at all depths generally matched the historical trend of decreasing temperature with increasing depth and revealed no evidence of increasing lake water temperatures over the past four decades.
- In the spring of 2022, Bass Lake was noticeably warmer in the top 2-3m compared to water temperatures in this surface layer in all previous years.
- However, by August 2022, the temperature in the top 2m was similar to values recorded in the 1980s and 1990s and slightly cooler than in the two decades later (2000-2009 and 2010-2019).
- Based on these Bass Lake records, there appears to be some evidence of an increase in water temperature down to a depth of 3m in the two decades from 2000 to 2019; however, the more recent results indicate that this was not the case in 2022.

WATER CLARITY

As noted earlier, water clarity is not a driving variable in algal growth but rather a symptom of nutrient loading and eutrophication. In both Bass and Kahshe Lakes, this is more complicated as the linkage between water clarity and nutrient loading with phosphorus is masked by the tea coloured waters associated with dissolved organic carbon (DOC). However, notwithstanding these limitations, both sampling programs have monitored clarity via the Secchi disc method for as long as we have data on total phosphorus. The 2022 results are summarized below:

- In contrast to the findings in previous years, water clarity in Kahshe Lake as measured by the DMM was slightly less in both 2021 and 2022 compared to the water clarity measurements from 2019. However, water clarity in both years was similar to historical clarity measurements.
- In looking at the MECP's LPP measurements, the trend of greater clarity compared to DMM clarity measurements that was recorded from 2011 through 2017 was not repeated in the years from 2019 through 2022.
- This may be related to the methodology for recording water clarity, as the DMM measurements are the average of two sampling events while the LPP measurements by the Lake Steward represent an average of 9-10 measurements at each site over the period from May through October. Another possible reason for the divergence is that DMM measurements are taken irrespective of weather conditions while those for the MECP LPP program are more typically taken during sunny days when water clarity is enhanced by sunlight penetration.

ALGAL GROWTH

Harmful blue-green algal blooms were confirmed in Kahshe Lake in both 2020 and 2021; however, no HABs were confirmed in 2022. In 2020, the bloom was located along the northern shoreline in the Oak Road vicinity and was investigated by staff from the MECP. In 2021, the first report of a bloom was in the east end of the lake (actually in the Kahshe River), but this was followed by reports of similar blooms in several areas of the lake, and as such, the alert was issued to cover the entire lake. Further details on these specific blooms and any others going forward have been described in greater detail in the KLRA Web's Water Quality portal and can be accessed via this link:

<https://kahshelake.ca/resources/Documents/Lake%20Steward/2022/Current%20Algal%20Bloom%20Status%20for%20Kahshe%20and%20Bass%20Lake-R3%20Feb2022-TCAccepted.pdf>

To assess how phosphorous levels in our lakes compare to those in other algal-impacted lakes in the Muskoka region, data from 2018 and 2019 were utilized. The main finding from this comparison was that out of 10 impacted lakes with available total phosphorus levels, five had levels well below those found in Kahshe and Bass Lakes.

These findings give cause for concern, as this trend towards increasing numbers of late-season harmful algal blooms throughout Muskoka does not appear to be directly associated with increasing levels of total phosphorus or nitrogen compounds determined via these early spring water quality sampling programs from the deep water of mid-lake sampling sites.

This apparent anomaly prompted the development of the KLRA-funded Near Shore Water Sampling Project (NSWSP) in 2021 and the findings from those water sampling activities identified a causal linkage between algal bloom development and water quality parameters, indicating the leaching of soil-borne and mobile nitrogen compounds from septic systems or lawns located near the shore which attract large numbers of Canada geese were involved. This appeared to be associated with higher intensity rainfall events characteristic of a changing climate which appear to be accelerating the nutrient leaching process.

The NSWSP findings are briefly summarized below:

- Mid-lake, deep water sampling in the spring of the year is a reasonable way to track long-term, historical changes in water quality but is not providing a true assessment of water quality in the near-shore environment where HABs have been documented.
- The mid-lake, deep water sampling also has failed to capture much higher total phosphorus levels in the east end of the lake, as there are no DMM sampling sites in that area.
- Levels of algal-friendly nutrients (phosphorus and nitrogen) are almost always higher than in the mid-lake areas and fluctuate significantly as the season progresses, further limiting the accuracy of the spring sampling of mid-lake sites in terms of assessing the potential for HAB development.
- The near-shore water chemistry for some algal-friendly nutrients were consistent with expected those known to be associated with effluents from human and animal waste sources and are known to be linked with the development of HABs.
- Although more study is warranted, the near-shore findings point to accelerated leaching and/or runoff of soil-borne nutrients due to a changing climate which is resulting in more intense rainfall events.

Calcium Depletion Summary

Decreasing lake water calcium concentration is an emerging concern for lakes on the Precambrian Shield in Ontario due to its impact on the reproduction and survival of zooplankton and other aquatic species that are important components of the aquatic food chain.

Levels of calcium below the growth limiting threshold of 1.5 mg/L have not been identified in the sampling of Kahshe or Bass Lakes. However, as the calcium concentrations in both lakes are only marginally above the limiting value and as this threshold would not be protective of all aquatic organisms, continued vigilance is necessary. The concern regarding a gradual decline in calcium concentrations and a shift in the population of essential zooplankton species across lakes in Muskoka was discussed, and a late season population explosion of *Holopedium* was documented in Kahshe Lake in both 2021 and 2022. Although the overall ecological impacts of this *Holopedium* dominance are not

known, they certainly represented an uncomfortable experience by many swimmers in Kahshe Lake in 2021 and 2022.

Lake Acidification Summary

The waters of Kahshe and Bass Lake have acidity (pH) levels that are within a normal range and above the lower limit of the optimum level where aquatic impacts may begin to be shown. There is also no evidence of an increase or decrease in acidity over the 15 year monitoring period.

While the pH findings represent good news, it should also be recognized that the waters of Kahshe and Bass Lakes have low levels of alkalinity, and as such, are more susceptible to acidification, as the ability of the water to buffer the acid input is low.

As such, while there is currently no concern, continued monitoring of the acidity is warranted.

Metals and Other Chemical Contamination Summary

The analysis of several additional anions, cations and other chemicals by the DMM has identified no pressing issues from an aquatic health aspect. While there were some minor exceedances of chronic (long term) benchmarks established by the MECP and other agencies to protect aquatic receptors, most of these exceedances were detected in the early years of the sampling program and appear to be related to sampling or laboratory artifacts, as more recent sampling has shown concentrations that are in the expected range for non-impacted surface water bodies in Ontario. In several cases (cadmium, silver and selenium), the laboratory detection limits are similar to or slightly below the aquatic protection value, and as a result, the non-detected levels of these substances are either just above or below their respective aquatic benchmarks. This situation was exacerbated by the increase in DLs in 2021 and 2022. Aluminum in Bass Lake also exceeds the aquatic benchmark in several years; however, as noted, the benchmark consists of a range in values and must be evaluated based on the pH and DOC concentrations in lake water. Based on these findings, these substances will be followed carefully in future monitoring to ensure that the waters of Kahshe and Bass Lakes are safe from an aquatic perspective.

The other finding from this data set is that there are numerous parameters that, like total phosphorus, are slightly or noticeably higher in Bass Lake compared to Kahshe Lake. There are also a couple of parameters (silicon and N-NO₃) where the opposite (Kahshe higher than Bass) is documented. The reason for these differences in the two lakes is unknown but may be helpful when the DMM Causation Study of both lakes is undertaken.

Dissolved Oxygen Depletion Summary

Dissolved oxygen (DO) in lake water is important for two main reasons:

- It is essential for the survival of all aquatic organisms, and
- A lack of oxygen in the lower layers of the lake (referred to as being anoxic) can cause mobilization (release) of phosphorus from sediments.

Dissolved oxygen is influenced by seasonal changes that factor into lake stratification, the process whereby lake water is turned over (mixed) in the late fall and again following the winter ice melt and then begins to stratify through the spring, summer and fall as water temperature increases at the surface and DO levels decrease with increasing depth.

The DO findings for spring and summer at different water depths in both Kahshe and Bass Lakes for 2022 are summarized below. In the evaluation, the results are compared to the mean results historically, broken into the 1980s & 1990s, 2000-2009 and 2010-2019.

- In both lakes, the Spring DO levels are relatively stable across all sampling depths, reflecting the action of vertical mixing from the turnover of cold and warm water from the fall through the spring.
- However, by early August, the 2022 DO levels are considerably higher than in previous years/decades down to around 5-6m depth and then level off or rise slightly with increasing depth down to 20m.
- More importantly from an aquatic health perspective, the DO levels from 2022 appear to follow the historical trend of falling below the PWQO at a depth of around 5m but do depart from the continued decline in DO with increasing depth observed in the 1980s and 1990s period by gradually recovering (increasing) in 2022, following the trend that was observed in the 2000-2009 and 2010-2019 decades. As such, while the findings of DO levels below the aquatic benchmark are of concern, the trend towards gradually increasing levels at depths below around 6m that has been happening after the 1980s and 1990s is good news.
- In Bass Lake, by early August, the 2022 DO levels are essentially similar to the two historical records of DO levels down to about 2m depth and then decrease gradually through the 3m depth, falling below the PWQO just below the 2m depth.
- From a biological perspective, unlike Kahshe Lake, there appears to be a trend towards DO levels falling below the PWQO at more shallow depths (just below 2m) than back in the 1980s and 1990s when DO crossed below the PWQO only at depths almost at lake bottom (just below 3m).

Benthic Health Summary

Benthic health assessment is now undertaken annually, as Kahshe Lake is now considered a 'Vulnerable' lake due to the appearance of HABs in 2020 and 2021. This involves sampling by the DMM's Biotechnician at established sites to determine which benthic macroinvertebrates are found. These benthos indicate the health of the riparian zone (section between shallow water and dry land) and the littoral zone (shallow water nearest to dry land). These two zones are especially important to lake health as they are impacted by snowmelt, runoff, sedimentation and other development activities.

Collected benthos are grouped into seven (7) different categories based on their typical response to environmental contamination and are then compared to the Muskoka average for relevance purposes and to detect changes over time in species richness and biodiversity. The 2022 findings are briefly summarized below:

- Richness was good and represents biodiversity within the lake and demonstrates that there is a healthy relationship between benthos.
- %EOT was very good and indicates a population of pollutant intolerant species, so having it this far above the Muskoka average is very good.
- %Chironimids which is an indicator of poor water quality was well below the Muskoka average, so this was a favourable finding.

The remaining four indicators (%Predators, %Shredders, %Collectors and the Hilsenhoff Index all were normal and serve to detect any major population deviations from the Muskoka average.

6.0 Main Summary and Conclusions

A comprehensive review and analysis of all historical environmental monitoring on Kahshe and Bass Lakes has now been completed and presented within annual Lake Steward Reports from 2012 through 2022. These documents as well as Executive Summaries each year have been posted on the KLRA website: <https://kahshelake.ca/Water-Quality>.

This report captures the findings from sampling and analysis of both Kahshe and Bass Lakes in 2022.

In an effort to simplify the reporting of a large amount of measurement and analysis data, the report has been structured to address the following issues/areas of potential concern for both Kahshe and Bass Lakes:

- Nutrients, Water Clarity, Temperature and Algal Growth
- Calcium Depletion
- Lake Acidification
- Metals and Other Chemical Contamination
- Dissolved Oxygen Depletion
- Benthic Health

To better understand the chemical and physical data that have been collected, the 2022 report includes an overview of the climatological factors that have the potential to influence lake conditions.

This comparison demonstrated that air temperatures in 2022 were generally similar to the three previous years and to the 30 year normal for most months, with the exception of much warmer conditions in May and to a lesser extent, August and September. In the case of precipitation, total monthly amounts were noticeably lower in May through July and above normal in August. The lower levels of precipitation in late summer in 2022 may have played a role in the absence of a blue-green algal bloom in 2022 as major late-season precipitation events in 2020 and 2021 appeared to have accelerated the leaching and run-off of algal-friendly nutrients into near-shore waters and the development of harmful algal blooms.

In 2022, the ice-out date was April 16 and the data for Kahshe Lake appear to generally follow the ice-out dates for the larger Muskoka Lakes, with no evidence of a trend towards earlier or later ice-out times on Kahshe Lake over this 135 years period.

A full discussion of the findings of DMM and MECP water quality and biological monitoring programs can be found in Section 4 of this report, and these findings are summarized in Section 5. Based on these investigations, the following conclusions have been reached regarding the six water quality indicators identified above.

Lake Health Parameter	Summary of 2022 Findings
Nutrients, Water Clarity, Temperature and Algal Growth	With one exception, the 2022 water quality monitoring of Kahshe and Bass Lakes by the DMM and the MECP has not identified any major water chemistry issues or trends in terms of algal friendly nutrients – nitrogen and phosphorus. The only exception was an increase in mid-lake total phosphorus levels at one location in Kahshe Lake and this has resulted in the 2022 levels at the DMM’s Main site near Hens and Chickens now

Lake Health Parameter	Summary of 2022 Findings
	<p>reaching the DMM’s Threshold level for Kahshe Lake. This likely due to mixing of higher phosphorus-laden waters via current flow from Bass Lake, as it is now known that the east end of Kahshe Lake has higher levels of total phosphorus due to its proximity to Bass Lake which typically has about twice the levels of total phosphorus.</p> <p>Trends in water temperature and clarity which can be indicators of favourable algal growth conditions also were examined and there was no evidence of a warming trend based on water temperature measurements dating back to the early 1980s. Water clarity also has remained fairly steady over this four decade period.</p> <p>And finally, the good news is that although the Simcoe-Muskoka area experienced HABs in 10 lakes/water bodies in 2022, there were no confirmed HABs on Kahshe or Bass Lakes in 2022.</p>
Calcium Depletion	<p>Decreasing lake water calcium concentration is an emerging concern for lakes on the Precambrian Shield in Ontario due to its impact on the reproduction and survival of zooplankton and other aquatic species that are important components of the aquatic food chain.</p> <p>The 2022 data confirm that there is no detectable trend towards decreasing levels of calcium in either Kahshe or Bass Lakes. However, as levels of calcium are fairly close to the aquatic growth limiting threshold of 1.5 mg/L and as this threshold value would not be protective of all aquatic organisms, continued vigilance is necessary.</p> <p>This is underscored by late season population explosions of <i>Holopedium</i> in Kahshe Lake in both 2021 and 2022. These pea sized, jelly-like orbs are not known to be toxic, but are an uncomfortable nuisance as they can be felt against your skin while swimming.</p>
Lake Acidification	<p>The waters of Kahshe and Bass Lake have acidity (pH) levels that are within a normal range and there is no evidence of an increasing or decreasing trend in acidity over the two decade monitoring period.</p> <p>While the pH findings represent good news, it should also be recognized that the waters of Kahshe and Bass Lakes have low levels of alkalinity, and as such, are more susceptible to acidification, as the ability of the water to buffer the acid input is low.</p>
Metals and Other Chemical Contamination	<p>The analysis of over 30 additional anions, cations and other chemicals by the DMM in 2022 has identified no aquatic toxicity/health issues. While there were some minor exceedances of chronic (long term) health protection benchmarks established by the MECP and other agencies in the early years, most of these exceedances were likely due to sampling or laboratory artifacts, as more recent sampling has shown concentrations that are in the expected range for non-impacted surface water bodies in Ontario.</p> <p>However, it should be noted that in several cases the laboratory detection limits are at or close to aquatic protection values, and as a result, firm conclusions regarding</p>

Lake Health Parameter	Summary of 2022 Findings
	<p>these substances cannot be drawn. This situation was exacerbated by the increase in some Detection Levels in 2021 and 2022</p> <p>In the case of aluminum, the aquatic benchmark has been exceeded in Bass Lake in several years; however, the benchmark consists of a range in values and must be evaluated based on the pH and DOC concentrations in lake water. Based on these findings, the levels of aluminum need to be followed carefully in future monitoring to ensure that the waters of Kahshe and Bass Lakes are safe from an aquatic perspective.</p>
Dissolved Oxygen Depletion	<p>Dissolved oxygen (DO) in lake water is important, as it is essential for the survival of all aquatic organisms. A lack of oxygen in the lower layers of the lake (referred to as being anoxic) also can cause mobilization (release) of phosphorus from sediments.</p> <p>Dissolved oxygen is influenced by seasonal temperature changes that factor into lake stratification, the process whereby lake water is turned over (mixed) in the late fall and again following the winter ice melt and then begins to stratify through the spring, summer and fall as water temperature increases at the surface and DO levels decrease with increasing depth.</p> <p>The DO at increasing water depths in both Kahshe and Bass Lakes for 2022 revealed that:</p> <ul style="list-style-type: none"> ▪ In Kahshe, the DO levels follow the historical trend of falling below the PWQO at a depth of around 5m below the surface. However, unlike the earliest data from the 1980s and 1990s, they begin gradually recovering (increasing) in 2022, following the trend that was observed in the 2000-2009 and 2010-2019 decades. This is good news in terms of aquatic life at lower depths of the lake. ▪ In Bass Lake, by early August, the 2022 DO levels are essentially similar to the historical records of DO levels down to about 2m depth and then decrease gradually through the 3m depth, falling below the PWQO just below the 2m depth. This is a concern from both an aquatic health and phosphorus mobilization from sediment perspective.
Benthic Health	<p>Benthic health assessment is now undertaken annually, as Kahshe Lake is now considered a ‘Vulnerable’ lake due to the appearance of HABs in 2020 and 2021. The types of benthos indicate the health of both the riparian and littoral zones as these areas can be impacted by snowmelt, runoff, sedimentation and other development activities.</p> <p>Collected benthos are grouped into seven different categories based on their typical response to environmental contamination and are then compared to the Muskoka average. The 2022 findings confirmed that species richness (biodiversity) was good and that species that thrive in good water quality were above the Muskoka average while species that thrive under pollution stress were below the Muskoka average, both of which are favourable findings.</p>

Based on the 2022 water quality and benthic monitoring of Kahshe and Bass Lakes by the DMM and the MECP, with a few exceptions, no major water quality issues or trends were identified. However, given the documented occurrence of HABs in Kahshe Lake in both 2020 and 2021 as well as the late season population explosion of a zooplankton organism (*Holopedium*) known to be associated with decreasing levels of available calcium in Muskoka region lakes, it is clear that the tracking of water quality via the mid-lake, deep water sites of the DMM and MECP is not providing a fully representative assessment of water quality in the near-shore environment where algal blooms have been documented..

In the case of Bass Lake, the DMM has identified it as a ‘Vulnerable’ lake and has undertaken a more comprehensive Causation Study in 2021. Hopefully, the findings from those investigations will shed light on the cause of the elevated total phosphorus which has been recorded in Bass Lake since monitoring by the DMM began back in the early 1980s. A draft of the DMM’s investigation was released in late 2022 and comments were provided by the KLRA. The final report has not yet been released.

So, for Kahshe Lake, where do we go from here?

Kahshe Lake also has been identified by the DMM as a ‘Vulnerable’ lake and a DMM-funded Causation Study will be undertaken when funds and staffing are available following the completion of Causation Studies on the first group of vulnerable lakes (including Bass L). Given the uncertainty regarding the implementation of a DMM-funded Causation Study and the concern of property owners regarding the late season HABs in 2020 and 2021, the KLRA funded a Conservation Committee project in 2021. The purpose of this study was to explore the chemistry of near-shore waters over the spring and summer season in an effort to better understand why Kahshe Lake has been impacted by HABs in spite of reasonably low and unchanged phosphorous levels reported by the DMM and MECP over the past 40 years.

The findings from this Near-Shore Water Sampling Project (NSWSP) have been published in a final report available on the KLRA Water Quality web portal. The NSWSP identified some very useful insights and linkages between our changing climate, its impact on water quality and the development of late season HABs in Kahshe Lake. Briefly, the NSWSP demonstrated that:

- Mid-lake, deep water sampling in the spring of the year is a reasonable way to track long-term, historical changes in water quality but is not providing a very accurate assessment of water quality in the near-shore environment where HABs have been documented.
- The mid-lake, deep water sampling also has failed to capture much higher total phosphorus levels in the east end of the lake, as there are no DMM sampling sites in that area.
- Levels of algal-friendly nutrients (phosphorus and nitrogen) tend to increase and fluctuate as the season progresses, further limiting the relevance of the spring sampling of mid-lake sites in terms of assessing the potential for HAB development.
- The near-shore water chemistry findings for some algal-friendly nutrients appear to be associated with effluents from human & animal waste sources and are known to be linked with HABs.
- Although more study is warranted, the near-shore findings point to accelerated leaching and/or runoff of soil-borne nutrients due to a changing climate which is resulting in more intense late season rainfall events.

Although we have virtually no control over the change that is affecting our climate, there are actions we can and must take to minimize the accelerated leaching of algal friendly nutrients to our shoreline water and thereby reduce the potential for future algal blooms. These actions have been thoroughly explored by the Conservation Committee and are summarized below:

- 1. Divert roof drainage and runoff from paths and other hard surfaces away from your septic system and the shoreline. If necessary, direct rain water into rock-filled drainage pits.**
- 2. Keep most of your shoreline as natural as possible with a zone of trees, shrubs or tall grass between the shore and any lawn area to discourage grazing by Canada geese and to reduce soil & goose poop runoff into the lake.**
- 3. Have a licensed professional pump out and inspect your septic system for failures and deficiencies every 3-5 years and more often for aging systems installed pre-2000. The Town will be inspecting in 2023, but we don't need to wait until then and be subject to system shutdown until failing systems are repaired.**
- 4. Don't use phosphorus or nitrogen fertilizers or cleaning agents anywhere near the shore.**
